

They Fit Like Silk

In buying rubber gloves you want a perfect fit; you want strength with flexibility; durability with lightness; and above all, you want gloves of quality to stand without deterioration, frequent sterilizations.

Massillon Rubber Co. Gloves

fill all of these specifications and more. The wrists are reinforced to prevent tearing; the fingers are tapering to give lightness of touch; and the special process by which these gloves are made guarantees them for one year against deterioration. Reinforced wrists have double strength.

A FREE OFFER

Send us the name of your dealer and 25¢ in stamps to cover postage, packing and insurance, and we will send you a pair of Massillon Rubber Co. Gloves FREE.

We can make any weight, rough finish

Dr. C. Frank Lydton's Surgery, Marshall Field Annex, Chicago

A Noted American Surgeon Selects Vitrolite

THE splendid reputation of the office of Dr. C. Frank Lydton in the Marshall Field Annex represents the highest recommendation of equipment and structural materials. Vitrolite is used for facing the wall for instruments, top and shelves in the Operating Room, Surgery and Research Laboratory.

Vitrolite was selected because it is absolutely septic—stainproof—acid proof and moisture proof—and on account of its brilliant polished pure white surface is easy to keep sanitary. Vitrolite is made in large slabs and is applied to wall and ceiling with a plaster cement.

Some Points In Its Favor

1 The LUNG MOTOR is the only physiologically correct resuscitating device on the market.

2 It has more successful cases to its credit than any other device of its kind

3 In cases of electric shock it is the only device that will resuscitate.

4 There is nothing complicated about its operation. It is simplicity itself

5 There is no hard physical labor involved in its operation—even a frail woman can work it.

6 No motive power of any kind is needed. It is purely a hand operated proposition and can be used anywhere under any circumstances

7 From every standpoint—humanity, economics, efficiency—it is a necessity

In the Mod

In the modern clinic there is always a LUNG MOTOR on hand ready for instant use. Physicians know that with this greatest of resuscitating devices available for any emergencies

To Aspirants for Success:

It is well known that the greatest advance in the control of disease has been through prophylactic and therapeutic immunization.

What in the entire history of medicine compares to the results achieved in the control of cholera, plague, small pox, hydrophobia, whooping cough, meningitis, typhoid fever, typhus and many other diseases by the use of vaccines?

Do you realize that equally wonderful results can be achieved in the treatment of pneumonia, broncho-pneumonia, rheumatic fever, bronchitis, puerperal sepsis, etc., with appropriate bacterins and that the physician of the future will be the one who is a skilled immunologist? If you are not acquainted with the rapid strides made in this wonderful field of immunization you owe it to yourself and your patients to become informed at once.

Dr. Sherman's New Book on Vaccine Therapy

Just off the press with 500 pages of live material. By the way do you know why few dead organisms injected under the skin will produce more immunity during an infection than the live organism causing the infection? This and many other things are rationally explained. **SEND YOUR ORDER TODAY**

Operative Midwifery

A Guide to the Difficulties and Complications
of Midwifery Practice

By J. M. MUNRO KERR, M.D., C.M. Glas.
Fellow of the Royal Faculty of Physicians and Surgeons, Glasgow. Professor of Midwifery and Diseases of Women, Anderson's College Medical School, etc.

Third Edition

I considering the various pathological conditions causing dystocia and the methods of dealing with them, the author has tried, as far as possible to indicate what is becoming more apparent every day that the art of midwifery can no longer be considered a subdivision of medicine, but must be regarded as a branch of surgery requiring thorough knowledge of surgical principles.

In the present edition the book has been carefully revised, and is now presented as a complete treatise on manual obstetrical conditions.

Octavo volume, 740 pages beautifully illustrated by 303 line and half-tone engravings. Extra morlin, price \$6.00 net.

The After-Treatment of Operations

A Manual for Practitioners and
House Surgeons

BY

P. LOCKHART MUMMERY, F.R.C.S. Eng.

Fourth Edition

In the present edition, much new matter has been added and the whole book brought completely up to date.

The chapter on Surgical Shock has been entirely rewritten in the light of more recent work on this subject.

The after-treatment of the more common and less serious operations is, as far as possible, described fully as these are the cases in which the after-treatment is most likely to be left to the general practitioner or house surgeon.

Small octavo, 284 pages, with many illustrations. Price, extra morlin, \$2.25 net.

On Modern Methods of Treating Fractures

BY

ERNEST W. HEY GROVES, M.B., M.D.
B.Sc., F.R.C.S.

Surgeon to the Bristol General Hospital

"My principal aims have been two. First, to show that the various methods of treatment should all be brought into our service as occasion requires, in stead of being regarded as independent, rival, or mutually destructive systems—and secondly to emphasize the necessity for mechanical accuracy and efficiency in dealing with what after all is largely a mechanical problem.

(Author's Preface.)

Octavo, 300 pages, illustrated by 136 engravings. Extra morlin, \$2.75 net.

Complete Catalogue on Request

The extent and varied character of our stock of medical books will be appreciated when we say that it ranges from early rare items of the 15th, 16th and 17th centuries to the latest monograph on special branches of surgery. It includes complete sets of valuable medical journals and in fact, practically every branch of medical literature.

We are always glad to have inquiries from medical book buyers however difficult their requirements may be and we welcome correspondence.

We will have a specially interesting exhibit at the Clinical Congress of Surgeons.

Don't fail to visit our Exhibit at The Clinical Congress of Surgeons in Philadelphia

Dr. Howard A Kelly's Stereo-Clinic

IT is universally conceded that the only way to keep posted on all the advances made in Surgery is to visit Clinics. The up to date surgeon must see the operation itself. The formation of Clinical Societies in various cities and towns as well as the Clinical Congress of Surgeons of North America, is proof of the growing necessity of seeing clinical work.

It is in recognition of these facts that

Dr Howard A. Kelly's Stereo-Clinic

was inaugurated and is now being published and kept up-to-date

A Few of the Many Expressions of Appreciation

Hugh H Young M D Johns Hopkins Medical School, Baltimore, Md

"If anyone studies the Stereograms made of my operations, he will see more than he can by witnessing the operation itself."

W Jackson M D F.R.F.P.S Nelson, Lancashire, England.

"I am sure you deserve the thanks of the whole surgical world for producing such valuable and permanent work, which will be the more appreciated the more it is studied."

H Augustus Wilson M D Prof of Orthopedic Surgery Jefferson Medical College Philadelphia, Pa.

"I am very deeply impressed with the value of the STEREO CLINIC as I find they give information that could only be obtained by being present alone as an operator who is doing the work. They are extremely graphic."

A. F Jones M D Prof. Surgery College of Medicine, University of Nebraska, Omaha, Nebraska.

"I have DR HOWARD A. KELLY'S STEREO-CLINIC and the stereograms are splendidly executed illustrating operations by many of our best surgeons. I most heartily recommend to every surgeon the STEREO-CLINIC."

Fred H Albee M D Prof Orthopedic Surgery University of Vermont, Adj Prof Orthopedic Surgery Columbia University New York.

"I must say that I believe that anyone will get a better idea of the technique from these beautiful stereograms than from the front row in the amphitheater. The perspective and detail is wonderful."

George W Dobbin M D College of Physicians and Surgeons, Baltimore, Md

"The pictures are the finest I have ever seen. It is certainly the most graphic method of showing operations and you deserve great credit for having followed them."

NEW BOOKS AND NEW EDITIONS

Joslin's Treatment of Diabetes Mellitus

NEW WORK
JUST READY

The new treatment of Diabetes—the Allen treatment—by means of fasting, and the importance of physical exercise for diabetic patients are fully discussed in this book. The section on Surgery will enable the surgeon to operate on diabetics without *worring them into care*. The section on Foods and Their Composition is so arranged as to make it unnecessary for physician owning this book to possess any other book on food values either for the treatment of diabetic or other patients. Standard recipes and diets for severe cases of diabetes are given, notably an appropriate diet for severe diabetic patients who are poor.

Octavo, 440 pages, illustrated. By ELIZABETH P. JOSLIN, M.D. Assistant Professor of Medicine, Harvard Medical School, Consulting Physician, Boston City Hospital, Collaborator to the Metabolic Laboratory of the Carnegie Institution of Washington, U.S.A.
Cloth, \$4.50 net.

Kendall's Bacteriology

NEW WORK
JUST READY

This work presents its subject in a new and interesting way. Since the importance of bacteria centers in that they do rather than what they are, the chemistry of bacterial activity is obviously an important aspect of the subject, especially in its relation to immunology and nutrition, and to the intestinal tract in health and disease. The most recent advances in bacteriology are incorporated.

Octavo, 457 pages, with 40 engravings and colored plates. By ARTHUR L. KENDALL, Ph.D. Dr. P.H. Professor of Bacteriology, The Northwestern University Medical School, Chicago.
Cloth, \$4.50 net.

Warren's Surgery

NEW WORK
JUST READY

Special features of the book are the sections dealing with subjects in which great advance has been made in the last few years. A clear account is given of the best methods at present in use and very helpfully the author directs attention particularly to those which in his experience have proved sound and satisfactory. The *Surgical Anatomy* of and the *Methods of Diagnosis* appropriate to the various regions and organs also receive full consideration.

Two octavo volumes of about 750 pages each. 150 illustrations. By RICHARD WARREN, M.D. M.Ch. Oxon. F.R.C.S. Assent and Surgeon to and Teacher of Clinical Surgery, The London Hospital, Senior Surgeon to the East London Hospital for Children, Examiner in Surgery at the University of Oxford.
Cloth, \$7.50 net.

Cryer's Internal Anatomy of the Face

NEW 2d EDITION
JUST READY

In the preparation of this edition the text has been thoroughly and carefully revised to meet the requirements of those making special studies upon or operating on the region of the face. New matter has been added to the extent of about 60 pages.

Octavo, 496 pages, with 377 engravings. By M. H. CRYER, M.D. D.D.S. Professor of Oral Surgery, University of Pennsylvania, Chief Surgeon to Philadelphia General Hospital.
Cloth, \$4.50 net.

Davison & Smith's Autoplastic Bone Surgery

NEW WORK
JUST READY

The authors have endeavored to place the subject on a practical working basis by presenting in concrete manner the results of their own clinical and experimental work in autoplastic bone-surgery. They have further succeeded in boiling down the voluminous literature of the surgery of bones in such a way that the reader may draw his own conclusions as to the efficacy of the various methods in terms advocated by authorities. Repair of intractable, recent simple fractures by autoplastic transplantation of bone is fully described and is an important part of this work.

Octavo, 496 pages, with 74 illustrations. By CHARLES DAVISON, M.D. F.R.C.S. Professor of Surgery and Clinical Surgery, University of Illinois, College of Medicine, Surgeon to Cook County and University Hospitals, Chicago, and FREDERICK D. SMITH, M.D. Clinical Pathologist to University Hospital, Chicago.
Cloth, \$4.50 net.

Hayden on Venereal Diseases

NEW (4th) EDITION

The author has emphasized the practical clinical aspects of the subjects under discussion. On those methods of diagnosis and treatment he has included which his personal experience has proved to be useful and efficient. The number of illustrations has been more than doubled and most of them are original. The text has been completely revised and in large part rewritten.

12 mo., 226 pages, with 155 illustrations. By JAMES R. HAYDEN, M.D. Professor of Urology in the College of Physicians and Surgeons, Columbia University.
Cloth, \$3.50 net.

SURGERY, GYNECOLOGY AND OBSTETRICS

AN INTERNATIONAL MAGAZINE PUBLISHED MONTHLY

VOLUME XXIII OCTOBER 1916 NUMBER 4

CYSTITIS SEXUS FEMINAE

WILLIAM FRANKLIN HATHORN, M.D., D.D.

PERHAPS fifteen years ago the most encountered bladder ailment of which I am now able to treat is a large and common one. Neither at that time nor more recently have I found any adequate account of it in the literature. These patients have been treated in a symptomatic way but I do not believe that there be any clear understanding of the mechanism. That I believe myself to be the primary report.

In all I have seen approximately fifty cases. Most of them have been merely lost sight of. No satisfactory series of cases is now available except in a few recent ones. In many a comprehensive chart recorded but never ever made. The case have occurred in my own personal large collection with other physicians and in hospital and in private service. Because of the hopelessness of drawing in worth while conclusions from such fragmentary record I have abandoned that idea altogether and shall simply cite the typical history, course and procedure and present a few exceptional and picturesque views in color that are a true reproduction of picture seen in real cases.

My observation and conclusion then are in the way of generalities with however some obvious and definite features. My excuse for such a generalization is simply to call attention to what I believe to be an un-

truthful illustration of a disease that may be helpful to many and ultimately to the patient.

All but not many have been treated with medicine and but none with surgery. These symptoms are in the nature of a continuing drawing and mounting pain.

In the history resemble me why I was not seen in the male. My assumption is that I have felt that the hyperplastic process is a different kind of obstructive symptomatic that might break the period of the bladder. Moreover reported in the literature with it a complicating trauma and procedure but since may be peculiarly contributory cause. Certainly I have not seen the more highly pitched infection of the bladder in the male bladder that prevail in these age period.

Let me briefly cite a typical history. A woman long past the menopause in her several children in reasonably good general health came with bladder complaint. She will most likely deny any history of bladder trouble in earlier life. The symptoms will have arisen gradually without acute onset but will persist with variable periods of comfort or distress throughout the entire life of the patient. The prognosis now implies then in essentially chronic disease. Probably a bladder once succumbing to such arophic change that which is added infection of varying types can never be restored to better

than a merely comfortable condition. Attacks will recur with lowered general resistance bad weather conditions etc.

Its first occurrence is as a rule late after sexual life has terminated. There comes a gradual recognition of undue frequency of urination with tenesmus and burning. From time to time in its course the acute exacerbations may be severe and occasion much loss of sleep and worry resulting in distinct physical and mental impairment. Such sharp attacks may persist for weeks, followed by months of comparative comfort. The urine at its worst, may be clouded with mucus and pus, and occasionally though rarely blood stained. I have never seen a urine that was grossly thick and ropy with pus and mucus, as we often see it in cystitis cases in younger individuals and in old prostatics.

The bacteriological findings have been variable and in no way consistent. Staphylococci are practically always in evidence, colon bacilli and allied forms occasionally in one case a chain bacillus whose place in the nomenclature we never determined. Tubercle bacilli we have never found to be a factor in spite of the sometimes suggestive appearance. The smegma bacillus was almost invariably present unless excluded by care in procuring the specimen. In short, in those cases that we have studied a determinative infection has not been identified. It may not be a specific infection and this is our belief but a condition developing after many differing bacterial onslaughts in bladders already weakened by the processes of senile decay. Again, many of the forms that we find may be saprophytic there as a result of favorable soil conditions rather than as causative factors.

One of our active workers along the lines of surgical pathology suggested that I might find these cases to be secondary to various degrees of prolapse following the lacerations and relaxations of pregnancy. He thought that the prolonged air and clothing contact with perversion of secretions would in part account for the senile vaginitis and that this might be the primary source of infection with the bladder condition secondary. Certainly in several of my more recent cases this

has not been true and I am skeptical of it as definitely etiological.

One of the illustrations here shown is an extreme case in an unmarried woman of sixty four my only exception to the rule of the multipara. Here the vagina would only admit the little finger and there was nothing of relaxation or prolapse.

Often the bullous patches are sharply outlined in grouping from healthy perfectly normal bladder mucosa, as distinctly so as a Zoster eruption on the skin. This has suggested the possibility of its being akin to a recurrent chronic Herpes. Without going into lengthy discussion this theory hardly appeals to me as being adequate to explain the allied changes in the rectal and vaginal mucosae.

Almost without exception the condition is common to bladder, vagina, and rectum simultaneously. The clinical picture of senile vaginitis is so common that I shall not take time to comment on it except to say that it is always present and recognized that it most often receives all the attention and treatment for relief of the sometimes vague pelvic distress when it is only one of the triad of troubles.

The vaginal change is usually looked upon as a shrinkage of subcutaneous tissues with atrophic disturbances in the epithelium and resulting painful erosions or even ulcerations. Add to this bacterial invasion with inflammatory exudates and the future course is not difficult of imagination. If this brief paragraph is true applied to senile vaginitis, I believe it holds equally true of the accompanying bladder change and of the almost consistently present degeneration of rectal mucosa.

The vagina has not been included in the accompanying illustrations in spite of its invariable participation. I have presented however the rectal picture to accompany each bladder drawing. The rectal mucosa has varied in its appearance all the way from multiple punctate erosions to large distinct punched out areas of ulceration on an otherwise normal pink velvety base but still a darker ground shade than applies to a normal bladder.

At this point the question of syphilis might

Fig. 1. Bladder, post mortem

Fig. 2. Bladder, post mortem

propriety. I would reply that in most instances I studied myself from behind, even when I had my first disease and in recent years have repeatedly found the view correct, although not always Weismann.

The prostate has not exactly parallelled the view that benign prostatic hypertrophy or adenitis degenerates into carcinoma, but it might be counted for in the traumatic etiology, and the greater likelihood of a venous metastasis.

Autopsy has never been obtained in a malignant bladder cancer, and with this pathological fact before me in any case under my direct charge, and the conclusion is that it can hardly be regarded as even a tributary to a fatal termination.

If any actual histopathological tubercle has been made elsewhere and are available applying to the vaginal wall in some vagina, I believe that in all essential the findings there would correspond very closely to the result in bladder like in the group of us.

The cystoscopic appearance in two recent cases has presented a rather remarkable likeness to tubercle, yet the elevated nodules as I have been in the habit of calling them in individual cases contained evidently clear serum and in such case that I have supposed your fat mistake to be my fault.

the other appeared but helped not him to see in them with the cystoscope, but that the entire bladder is covered with exactly tubercle in pathologic. The microscopic appearance is entirely that which has been mentioned in presenting the plot. One illustration here, and the other will apply to that which is to be applied in the study of the bladder. In two of these cases, yet in the present examination, the vessel in the structure of the bladder, and the other three with the bladder appear in the bladder, and the extent of the study.

Often the cystoscopic picture is given by the plot, but it is not the same, but by the time of the fullness, but the term has been merely a histological application of the word in the present study, and it is not a type of cystitis, but tubercle, and in more strictly to hyperplastic picture.

The disease is not in the bladder, but in the bladder, however, which is not the same, where the bladder has been run in remarkable parallel and with a generally uniform symptomatology. The cystoscopic picture varies at different times, but in the end characteristically some occur at two months, ranging from an acute vascular inflammation to a mild chronic.

Degenerative changes are recognized

Fig. 6. Case 3. Superficially eroded appearance in patches throughout rectal pouch. Accompanies Fig. 5

in other mucous membranes. Bronchitis in the old becomes almost the rule. A chronic conjunctivitis with thickened and everted lids is all too common. Nasopharyngeal catarrh in the old becomes the bane of the family physician. Perhaps this bladder difficulty has simply to be added to that group.

The general management of these old women will be apparent the best of general care and hygienic control. The usual hot boracic irrigations are quickly beneficial. Argyrol in instillation is helpful. The rectal and vaginal irritation can perhaps best be met by the hot alkaline douche the interval of douching being gauged by the comfort obtained. Vigorous local treatment, such as application of strong silver. I have felt to be out of place since the problem seems to be one more of comfortable management than of cure. Pure liquid guaiacol internally is a drug possessing almost specific properties. It almost invariably brings remarkable and quick relief from the frequency of urination with tenesmus and burning when given in five to ten drops doses after each meal. Its use is in a way empiric. Some one has claimed that its benzoic acid radical is broken up and eliminated by the kidneys as hippuric acid. This being a normal urinary acid may play some definite part in the relief which we do not pretend to explain. It may be resorted to whenever discomfort is experienced

and taken for indefinite weeks or put aside perhaps for many months during the intervals of comparative comfort.

To discuss cellular and tissue changes due to age decay along purely biological lines as has been so ably done by Metchinkoff and many others is not my province yet I do feel that in this group of cases has been overlooked a pathological entity worthy of better recognition and a name. Tentatively I suggest *cystitis senilis feminarum* for lack of a better.

CASE 1. Mrs. W. age 60, multipara previous health good first experienced bladder symptoms at 64. At that time I found cystoscopically practically the same condition as when examined recently. At this later examination Fig. 3 (frontispiece) was taken, which gives the typical patchy grouping of vesicles seen at the height of attack. She has had several long periods of complete relief during these years. Figure (rectal) accompanying shows distinct elongated ulcerated fist above the internal sphincter bleeding on touch with a cotton swab.

CASE 2. Mrs. C. age 60 multipara previous health good mild bladder symptoms presented about the age of 50. Some years later was cystoscoped, the bladder showing irregular patchy ordem. Recently during an interval of comfort Fig. 3 (frontispiece) was taken and presents the typical pigmented appearance and chronically thickened vessel walls remaining after repeated cut excoriation. Figure 4 shows an ulcerated eroded area in the rectum. This patient has suffered from *hemorrhoids* for twenty years.

CASE 3. Mrs. O. age 58 mother of one child. Note that she has not menstruated since that childbirth thirteen years ago (cause unknown). During these years she has grown very heavy until her obesity has become a burden to her. Bladder symptoms first developed nine months ago. There have been short intervals of relief. Figure 5 (frontispiece) taken during an exacerbation, shows the typical vesicular patchy lesion at the height of an attack. This is the one exception to my series, in point of age yet here we had years ago atypical or pathological menopause, so that the "contradiction" after all not so great. Both vagina and rectum present superficially congested erosive areas. Fig. 6 presents a granulated appearance of the rectal mucosa.

CASE 4. Mrs. L. age 68 multipara previous health good. At 56 slight bladder trouble first became evident with variable intervals of relief since. It has been more persistent during the last three years. January 3, 1906 she presented the most extreme cystitis of this vesiculated patchy form that I had ever seen. I brought her back March 5 to get picture, which is shown in Fig. 7

SPONTANEOUS EXCLUSION OF THE KIDNEY FROM CIRCULATION

$$\begin{array}{ccccccc} \text{BY CHAKLE} & \text{M HAKI} & \text{H K I} & \text{K I} & \text{M I} & \text{I A I} & \text{I} \\ & \text{I} & \text{H} & & \text{A} & \text{H} & \end{array}$$

May I think positively demonstrate that renal and ureteral lithiasis may entirely disappear a kidney in situ and at the same time exclude the organ completely. Such a kidney is entirely out of the ureter and is taken out in further treatment of the patient and ureter better out of the body than left in. If you will examine the specimen actually you will see the ureter is entirely excluded.

The part from whom the body was removed
 and the virgin mother and the child
 and the child who was taken to the
 N. 11 on August 4, 1885. She stated that the
 mother in the child was the same as the
 child in her child was the same as the

I received the notice Dr. Dall sent me
 by mail and I have the honor to reply
 to it by the same mode.

than a merely comfortable condition. Attacks will recur with lowered general resistance bad weather conditions etc.

Its first occurrence is, as a rule late after sexual life has terminated. There comes a gradual recognition of undue frequency of urination with tenesmus and burning. From time to time in its course the acute exacerbations may be severe and occasion much loss of sleep and worry resulting in distinct physical and mental impairment. Such sharp attacks may persist for weeks followed by months of comparative comfort. The urine at its worst may be clouded with mucus and pus, and occasionally though rarely blood stained. I have never seen a urine that was grossly thick and ropy with pus and mucus as we often see it in cystitis cases in younger individuals and in old prostatitis.

The bacteriological findings have been variable and in no way consistent. Staphylococci are practically always in evidence colon bacilli and allied forms occasionally, in one case a chain bacillus whose place in the nomenclature we never determined. Tubercle bacilli we have never found to be a factor in spite of the sometimes suggestive appearance. The smegma bacillus was almost invariably present unless excluded by care in procuring the specimen. In short in those cases that we have studied a determinative infection has not been identified. It may not be a specific infection and this is our belief but a condition developing after many differing bacterial onslaughts in bladders already weakened by the processes of senile decay. Again, many of the forms that we find may be saprophytic there as a result of favorable soil conditions rather than as causative factors.

One of our active workers along the lines of surgical pathology suggested that I might find these cases to be secondary to various degrees of prolapse following the lacerations and relaxations of pregnancy. He thought that the prolonged air and clothing contact with perversion of secretions would in part account for the senile vaginitis and that this might be the primary source of infection with the bladder condition secondary. Certainly in several of my more recent cases this

has not been true and I am skeptical of it as definitely etiological.

One of the illustrations here shown is an extreme case in an unmarried woman of sixty-four my only exception to the rule of the multipara. Here the vagina would only admit the little finger and there was nothing of relaxation or prolapse.

Often the bullous patches are sharply outlined in grouping from healthy perfectly normal bladder mucosa, as distinctly so as a Zoster eruption on the skin. This has suggested the possibility of its being akin to a recurrent chronic Herpes. Without going into lengthy discussion this theory hardly appeals to me as being adequate to explain the allied changes in the rectal and vaginal mucosae.

Almost without exception the condition is common to bladder, vagina, and rectum simultaneously. The clinical picture of senile vaginitis is so common that I shall not take time to comment on it except to say that it is always present and recognized that it most often receives all the attention and treatment for relief of the sometimes vague pelvic distress when it is only one of the trinity of troubles.

The vaginal change is usually looked upon as a shrinkage of subcutaneous tissues with atrophic disturbances in the epithelium and resulting painful erosions or even ulcerations. Add to this bacterial invasion with inflammatory exudates and the future course is not difficult of imagination. If this brief paragraph is true applied to senile vaginitis I believe it holds equally true of the accompanying bladder change and of the almost consistently present degeneration of rectal mucosa.

The vagina has not been included in the accompanying illustrations in spite of its invariable participation. I have presented however the rectal picture to accompany each bladder drawing. The rectal mucosa has varied in its appearance all the way from multiple punctate erosions to large distinct punched out areas of ulceration on an otherwise normal pink velvety base but still a darker ground shade than applies to a normal bladder.

At this point the question of syphilis might

Fig. 6 Case 3 Superficially eroded appearance in patches throughout rectal pouch. Accompanies Fig. 3

in other mucous membranes. Bronchitis in the old becomes almost the rule. A chronic conjunctivitis with thickened and everted lids is all too common. Nasopharyngeal catarrh in the old becomes the bane of the family physician. Perhaps this bladder difficulty has simply to be added to that group.

The general management of these old women will be apparent: the best of general care and hygienic control. The usual hot boracic irrigations are quickly beneficial. Argyrol in instillation is helpful. The rectal and vaginal irritation can perhaps best be met by the hot alkaline douche; the interval of douching being gauged by the comfort obtained. Vigorous local treatment, such as application of strong silver. I have felt to be out of place since the problem seems to be one more of comfortable management than of cure. Pure liquid guaiacol internally is a drug possessing almost specific properties. It almost invariably brings remarkable and quick relief from the frequency of urination with tenesmus and burning when given in five to ten drops doses after each meal. Its use is in a way empirical. Some one has claimed that its benzoic acid radical is broken up and eliminated by the kidneys as hippuric acid. This being a normal urinary acid may play some definite part in the relief which we do not pretend to explain. It may be resorted to whenever discomfort is experienced

and taken for indefinite weeks or put aside perhaps for many months during the intervals of comparative comfort.

To discuss cellular and tissue changes due to age decay along purely biological lines, as has been so ably done by Metchnikoff and many others is not my province yet I do feel that in this group of cases has been overlooked a pathological entity worthy of better recognition and a name. Tentatively I suggest *cystitis senilis femininarum* for lack of a better.

CASE. Mrs. W. ag. 60, multipara previous health good first experienced bladder symptoms at 64. At that time I found cystoscopically practically the same condition as when examined recently. At this later examination Fig. (frontis-piece) was taken, which gives the typical patchy grouping of vesicles seen at the height of attack. She has had several long periods of complete relief during these years. Figure (rectal) accompanying shows distinct ulcerated nodule just above the internal sphincter bleeding on touch with cotton swab.

CASE. Mrs. C. ag. 70 multipara previous health good mild bladder symptoms presented about the age of 50. Some years later was cystoscoped, the bladder showing irregular patchy edema. Recently during an interval of comfort Fig. 3 (frontis-piece) was taken and presents the typical pigmented appearance and chronically thickened vessel walls remaining after repeated acute exacerbations. Figure 4 shows an ulcerated eroded area in the rectum. This patient has suffered from a menorrhagia for twenty years.

CASE 3. Mrs. O. age 38 mother of one child. Not that she has not menstruated since that child birth thirteen years ago (cause unknown). During these years she has grown very heavy until her obesity has become a burden to her. Bladder symptoms first developed nine months ago. There have been short intervals of relief. Figure 5 (frontis-piece) taken during an exacerbation, shows the typical vesicular patchy lesion at the height of an attack. This is the one exception to my series. In point of age, yet here we had, years ago an typical pathological menopause so that the contradiction is after all not so great. Both vagina and rectum present superficially congested erosive areas, Fig. 6 presenting granulated appearance of the rectal mucosa.

CASE 4. Mrs. L. ag. 68 multipara previous health good. At 56 slight bladder trouble first became evident with variable intervals of relief since. It has been more persistent during the last three years. January 3, 1906 she presented the most extreme cystitis of this vesiculated patchy form that I had ever seen. I brought her back March 5 to get picture, which is shown in Fig. 7

(frontispiece) Greatly to my disappointment the appearance had entirely changed so that we were only able to get the interval picture with its apparent pigmentation of mucosa and increased network of vessels but no oedematous elevations or irregularities as seen previously. The rectal picture fails to show any of the lesions ordinarily found in these cases.

CASE 5. Mrs. McN., single, age 64. This is the only exception to my experience in this factor of childbirth but in as much as childbearing is regarded as only contributory, the explanations may be found more frequently than I have anticipated. Previous health only fair. Bladder symptom first appeared in February 1915 when he had a cystitis attack lasting three months. Since then he has had intervals of comfort.

A few of the vascular elevations have become purplular and one large clear bleb the size of a pea is apparent. The vagina and rectum both show advanced atrophic eroded areas.

Figure 8 (rectal) shows the same vascular lesion becoming purulent as found in the bladder. The artist has somewhat exaggerated the purulent character of these vesicles.

As suggested in an earlier paragraph the criticism may be offered that Fig. 8 is rather typical of tuberculosis. I admit the similarity but believe that during the coming summer months this bladder may be excised.

Fig. 8. Roentgenogram of the bladder showing a large, irregularly shaped mass, possibly a calculus or a large tumor. The mass is surrounded by a thin layer of tissue, and there are some smaller, more rounded masses visible within the main mass.

and will be found to correspond to Fig. 5 and 4. I have found this to be true in similar cases and bear in mind that this woman has had intervals of entire relief since the onset of her symptom and the history does not typically coincide with tuberculosis.

SPONTANEOUS EXCLUSION OF THE KIDNEY FROM CALCULI

By CHARLES M. HARPSTER, F.R.C. (M.D.), LACS. T. (D.O.)

Superior Toledo Hospital and Clinic, Toledo, Ohio

MY case I think positively demonstrates that renal and ureteral lithiasis may entirely destroy a kidney insidiously and at the same time exclude the organ completely. Such a kidney is entirely out of the urogenital system and is of no further use to the patient and surely better out of the body than left in. If you will examine the specimen carefully you will see the ureter is entirely occluded.

The patient from whom this kidney was removed was a female 37 years of age married and the mother of one child. She was referred to me by Dr. H. E. Noble, on August 4, 1915. She stated at the time of examination that she had had pain on her left side since her child was born about 12 years

ago. That for four or five years he had felt a mass on her left side which was gradually getting larger. For the last three or four months she stated she had had great pain at time of menstruation and that a large amount of pus was discharged from the vagina at time of menstruation. During the summer of 1915 had had spell of chills and fever and was compelled to remain in bed a part of the time. At times the pain in the left side was very acute and at other times would entirely disappear. The urine had been frequently examined and found free from any abnormal elements. During the period of her pregnancy the urinary symptoms were very marked and when voiding urine she had a bearing down burning pain. I made an examination of her urine and found it normal.

I referred the patient to Dr. Dolloway for an X-ray examination and I present the roentgenogram in which you will see the large calculus (Fig. 1).

Fig. Roentgenogram disclosing large calculus.

I catheterized the right ureter on August 6, 1905, and found no urine coming from the left kidney with catheter in the bladder and I was unable to pass catheter into the left ureter. The left kidney did not respond to any of the functional tests (phloridizin, phthalein indigo carmine). The right kidney was found to be normal.

A few days later I removed the specimen which is shown in Figs 2 and 3. The parenchyma of the kidney was as you see almost entirely destroyed. The cavity was filled with caseous mass. No tubercle bacilli were found on examination.

By operation the question arises whether we deprived the patient of a possible pus focus, since the organ had been spontaneously excluded by nature (Fig. 3). Perhaps only in so far as the ureter affected the vesical function could the presence of the organ have produced any clinical manifestations and even this is open to doubt. Buerger says:

Although this process of healing or exfoliation of the kidney (and, as it has also been termed, auto-nephrectomy) has been frequently noted as occurring in tuberculosis, it is not so well known that similar lesions may be the result of cerebral infection when the ureter has become obstructed for long time. So frequent is the development of the infectious type of lesion of the kidney when ureteral calculus is impacted for a long time that the

ureter that most of us will concede that total destruction of a kidney without pyonephrosis, without other manifestation of an infected pelvis or kidney parenchyma or without perirenal tissues is exceedingly rare.

It was our good fortune to obtain at an autopsy a specimen of a kidney and ureter which demonstrated conclusively that a kidney may be destroyed and excluded as it were in a silent fashion without giving any symptoms, when ureteral calculus or a ureteral calculus is impacted in the ureter for many years. In reviewing the literature but sparse mention of these facts could be found.

B. Rank in an article entitled "Concerning a Case of Healed Hydropyonephrosis" describes a case of infected hydronephrotic kidney which by virtue of an obstruction situated high in the ureter became converted into a sac filled with cheesy mortar like material. The kidney was obtained at an autopsy of a man who died of apoplexy. The foetal lobulations were fairly well marked by furrows separating many spherical protuberances the latter varying in size from a hazelnut to a walnut. Upon section the kidney which was hardly enlarged, was found filled with a cheesy mass of cement like consistency. The parenchyma was practically gone there being hardly any renal substance left except for remnants in the membranous walls and in the connective-tissue septa. Only at one point was there a small zone of tissue less than 1 cm in diameter. In short the specimen denoted the following pathological history: that a hydronephrotic sac had evidently become the seat of suppurative inflammation was thus converted into pyonephrosis, the purulent contents becoming finally changed into inspissated cheesy masses.

In discussing the causes of the hydronephrosis in this case the author concludes that the obstruction must have resided somewhere in the uteropelvic junction and inasmuch as no evidence of concretions or calculi were present he believes that either an inflammatory swelling of the mucous membrane or a calculus that had subsequently passed could have brought about the condition.

Vierteljahrsschrift für Praktische Anatomie, etc. Berlin, 1905, 15.

Fig. 3. Specimen removed from the patient.

Fig. 4. Specimen removed from another patient.

From a study of the author's report it seems to us most likely that the hydro-nephrosis could be best explained on the basis of an occlusion of the ureter by a calculus that had been arrested for a long time but had finally been expelled. The process of renal destruction as is seen in tuberculous of long standing where kidney tissue disappears and pseudocyst may form is often encountered where the calyx has become completely stenosed. With an obstruction of a calyx it is not frequent to see complete disintegration of the corresponding segment of the kidney and the conversion of the affected region into a sac filled with cheesy material or turbid fluid. In this way some of those cysts of the kidney may be accounted for the pathogenesis of which has given rise to so much comment and discussion. There

are those who doubt the existence of tuberculous cyst of the kidney. Hertz Boyer however describes two types of tuberculous cyst. First true cyst of the kidney in which epithelium covers the cavities and which coexist (renal tuberculosis) and secondly pocket which are the result of obstruction of a urinary passage of the kidney, as where a calyx is completely occluded. If the occluded zone is healthy a simple hydro-nephrosis is the result and contents of the cavity will be clear fluid. If on the contrary this area be the seat of a tuberculous process the cavity will become filled with cheesy material and this will become modified later on either into a putty like mass or it the material be absorbed into a fluid which contain some whitish particles and detritus.

DIVERTICULA OF THE URINARY BLADDER

By G. J. THOMAS, M.D., ROCHESTER, MINNESOTA
From the Mayo Clinic

THE frequent occurrence of diverticula of the bladder as observed in the urologic department of the Mayo Clinic has suggested a clinical study of the operative, non-operative, and post mortem cases since 1908.

Embryology. A review of the literature and textbooks of embryology as to the early development of the bladder is confusing. Many of the early writers are of the opinion that the anlage of the bladder is a differentiated portion of the allantois and is derived from this structure. Later writers, however, hold that the bladder is formed from the cloaca, a blind sac which is a dilated portion of the primitive gut caudal to the allantois. The cloacal membrane probably divides this sac into a ventral or large portion which becomes the urogenital sinus, and a dorsal smaller portion which becomes the rectum. Irenius (1) however from his dissections thinks that a saddle-like partition between the primitive gut and allantois grows caudally and divides the cloaca into dorsal rectum and a ventral primitive urogenital sinus. The partition thus made fuses with the cloacal membrane and divides it into the anal membrane of the gut and the urogenital membrane of the urogenital sinus. The mesonephric ducts which opened into the cloaca now open into this sinus. The buds forming the ureters spring from the mesonephric ducts near their insertion into the cloaca. As the urogenital sinus gradually becomes separated and differentiated from the rectum, certain absorptive changes take place in the proximal ends of the mesonephric ducts and primitive ureters. They become dilated and are taken up into the wall of the sinus, and as the absorption continues the ends of the ureters develop a separate opening and become separated from the ducts. The area between the ends of these two sets of ducts later becomes the point of division between a larger cephalic part of the sinus or the anlage of the bladder

and a smaller caudal portion which becomes the urethra.

Etiology. The etiology of these sacs from an embryologic standpoint can probably be explained as follows. The diverticulum so frequently seen around the meati may be anomalies of mesonephric duct buds which normally form the ureters etc. as Cabot and Binney pointed out from Huntington's case. Since portions of the wolffian ducts are taken up into the bladder and form a portion of it, anomalies of development may occur along the trigone and floor of the urethra as far as the ejaculatory ducts. The mucosa of the bladder is largely endodermal in origin except the trigone which together with the floor of the urethra is mesodermal. The failure of the urachus to close may account for some of the sacs at the roof of the bladder. These observations indicate that anomalies of embryologic development may at least predispose to the formation of these diverticula since most of them occur where fusion takes place between the different embryonic tissues. The location of the openings is most often in the areas where anomalies may be expected. The rôle that obstruction plays in the formation of these anomalies is not clear but clinically in a large percentage of cases it seems necessary for the development of symptoms.

Diverticula may be divided into two groups: congenital and acquired.

1. The congenital may be divided into (a) hour-glass bladder the strangulation may be above or below the ureters (b) double split or blind bladder. In this type the separation reaches to the apex of the trigone and both cavities open into a common urethra or a double urethra may be present.

2. The acquired type may be divided according to their etiology into (a) intra uterine (b) obstacles to urination (most frequent) and (c) traumatic.

The true congenital variety as observed

Fig. Small diverticula, probably congenital

ney containing stones was diagnosed from roentgen and cystoscopic findings. About one half inch anterior to the right ureter and toward the median line was another opening which could admit the end of the small finger. Upon observation, apparent spurts of fairly clear urine could be seen but these seemed to be synchronous with respiration. A catheter was passed with apparent ease and did not feel as if it coiled up. Argylol was injected into the bladder and a cysto-ureterogram was made. This showed a sausage-shaped shadow extending from the bladder to the bony pelvis of the right side where it was lost (Fig. 1). A had a passing catheter was passed into the right ureter which was found in a normal position and did not empty into or have any connection with the normal cavity. This patient had had a pelvic operation, which trauma of the bladder may have occurred and which might have been the etiologic factor in producing the same.

In the diagnosis of diverticula of the bladder in patients having suggestive symptoms Garratt (8) makes it a practice to distend the bladder with an opaque medium.

He believes that the diagnosis can easily be made by this means, and that it should be used routinely because in many instances cystoscopic findings are not positive.

In operating on a case of hour glass bladder Squier used two large clamps through the diverticulum opening and by resection between the clamps and stitching up the cut edges a large bladder or sac was made. He does not recommend this operation in all cases but thinks it applicable when the diverticulum is of the hour glass type.

In Young's (9) case in which there was a papilloma, he used a circular incision made from the vesical side surrounding the opening of the diverticulum. By blunt dissection the surrounding tissues were dissected off and it was necessary to remove a piece of the peritoneum. The peritoneum was closed through the vesical opening. This method is suggested by Young to remove diverticula and tumors which are situated on the posterior wall of the bladder and behind the ureteric openings.

Lower (10) suggested the introduction of a gauze strip into the sac to simulate a semi-solid tumor which makes its size easily seen and facilitates its removal. Edwin Beer (11) suggests the introduction of catheters into the ureters before operation is begun so that the ureters are easily found and constantly in view especially where transplantation is to be done.

Lerche (12) by means of a rubber bag attached to the end of a catheter and distended after introduction into the neck both increases the size of the diverticulum and makes resection easy. Lerche reports the following routes for radical operation:

- A Vaginal route
- B Sacral route
- C Suprapubic intraperitoneal
- D Suprapubic extraperitoneal

The various simpler methods which are used are:

- A Incision through the vaginal wall and drainage.
- B Establishing of fistula by sewing to the skin.
- C Peritoneal drainage behind bladder.
- D Peritoneal drainage of bladder.

Fig. 2 Large diverticulum in the right wall with flattened shadow projecting in that of the bladder

Fig. 3 Shadow showing a diverticulum which had been carefully injected with argyrol through a lateral catheter. Argyrol still in place in the bladder

E. Forceful stretching of the orifice of diverticulum

F. Curettement of mucous membrane of the diverticulum and suture of the latter without drainage

G. Invagination of diverticulum and bladder freshening of the margin of the orifice and closure intraperitoneally

I. Division of the walls of the bladder and diverticulum and suture of the cut walls

J. Suprapubic drainage

Engelisch (2) reports fifty-seven cases of diverticula up to 1904 in which there was perforation or rupture. He divides the cases that are most liable to perforation or rupture into four classes: (1) Chronic type with accumulation of pus and mucus; (2) acute suppurative; (3) ulcerating and gangrenous; and (4) perforating. In his opinion the location of the opening of the diverticulum in the bladder and its size are important factors entering into subsequent inflammation, perforation, etc.

In cases collected by Fischer there was a mortality in operative and non-operative

cases of 66 per cent in operative cases, 40 per cent and in non-operative of 84.5 per cent.

From January 1906 to November 1913, twenty-seven cases of diverticulum of the bladder have been observed in the Mayo Clinic. Fourteen of these patients were operated on, seven were not operated on, and six cases were found at autopsy. The average age of these patients was 51+ years, the youngest 18 and the oldest 73. The average age at onset of symptoms was 43+ years. Other than these numerous cases were observed which were regarded as false diverticula, probably the result of mechanical obstruction or inflammatory changes. These cases are not included in this report.

Previous diseases. Of these twenty-seven patients six (22 per cent) gave a history of urethral infection and two (7 per cent) had infection about the urethra associated with stricture. Five patients (18 per cent) had had previous operations, two for prostatic obstruction and three some operation on the bladder for drainage or exploration. Six (22 per cent) had trauma of the bladder, suprapubic area or of the perineum. The trauma to the perineum in two cases was the cause

of obstruction which preceded the symptoms. The four remaining patients gave good histories of onset of symptoms immediately following the trauma of the bladder.

Urinary symptoms. Difficulty of urination was present in nineteen instances (70 per cent) and was noted in eleven (40 per cent) as the first symptom. In nine there was retention and catheterization had to be resorted to before urine could be passed. In three there was incontinence. Frequency was a first symptom in nine (33 per cent) and was the predominate symptom in twenty-two. Hematuria was the first sign observed by the patient in two instances (7 per cent) while macroscopic blood was observed at some time during the history in eight (29 per cent). We were able to obtain a history of repeated urination from one patient only a symptom which has been frequently noted in published reports. In only two of our patients the symptoms began in childhood.

Clinical data. A suprapubic tumor was palpable in only three cases (11 per cent) in none was a flank or rectal mass observed. In eleven cases (40 per cent) a noticeable loss in weight was reported and this seemed to be the most common clinical finding. In six (22 per cent) the general loss of strength was graded as three on a scale of four.

Cystoscopic data. Cystoscopic examinations were made in nineteen of our patients. In sixteen (84 per cent) there was a marked degree of cystitis. In three (15 per cent) cancer was found in the bladder. In one case at post mortem a cancer was found in the diverticulum and was the cause of a perforation. Stones were found in the bladder in four (21 per cent) in one they were found with a cancer. There were three cases with multiple small stones in the diverticulum. Urethral stricture was noted in three (15 per cent) and was thought to be an etiologic factor in the production of the diverticula. In eight (42 per cent) the prostate was enlarged enough to cause obstruction to urination.

Location of opening of diverticulum. The opening of the diverticulum was found near the meati in six of the twenty-seven patients on the right side in two and on the left in

four. In six others the opening was found on the floor of the bladder in two near the urethra in four on the posterior wall in two in the dome in three the lateral walls were involved. In one an hour glass condition was found. In the three remaining cases the opening was on the posterior wall or base. In four cases there was more than one diverticulum. In thirteen cases generalized trabeculation of the bladder was present.

Röntgen-ray. A cystogram was made in sixteen cases ten showing positive findings. In our opinion a routine cystogram in suspected cases in which there is difficulty of urination not otherwise diagnosed either with or without the aid of the cystoscope will demonstrate a diverticulum in a large percentage of cases. Care must be taken in exposing the plates. Many shadows of diverticula are missed when the radiogram is taken in the ordinary anteroposterior position. Exposures should be made with the tube at different angles so that the shadow of the sac is not superimposed on that of the bladder. A coiled shadow-casting catheter or bougie will definitely outline a sac when shadow-casting fluids cannot be used. Care must be taken in the introduction of catheters into these sacs, and overdistention from injected fluids must be avoided because perforation of the diverticulum might occur (Figs. 2, 3, 4, 5 and 6).

Urinalysis. Pyuria was present in seven cases and gross blood was noted in three.

Medical treatment. Symptomatic treatment does not relieve patients of their symptoms and should be used only when surgical measures are contra-indicated. Temporary relief is sometimes obtained but recurrence is rare.

Surgical treatment. In fourteen cases some type of operation was performed. In six the diverticulum was resected. The extraperitoneal operation was done four times and the intraperitoneal two. A preliminary drainage was done in two cases preparatory to a resection. In six instances a drainage operation only was done or the diverticular opening was enlarged. In one case a septum was removed and in one a diverticulum was

Fig. 4 Multiple diverticula in the lateral wall of the bladder

Fig. 5 Multiple diverticulum in the lateral wall of the bladder

dissected loose and its opening enlarged so that the drainage was improved or complete.

Complications. In three instances cancers were removed; one occurred with an hour glass contracture of the bladder; the mass in the upper chamber. Stones were removed in three patients; two having stones in the diverticula. It was necessary to remove the prostate in six instances. The prostates all proved to be benign. Dilatation of the ureter was found in one. In only one case was there evidence of perforation or of peritonitis.

This occurred in a man of 60 years who came to the Clinic complaining of a long standing skin trouble. For a number of years he had slight difficulty with urination and was quite sure that he was not emptying his bladder. He was in very poor physical condition and a complete examination was not made. Urinary difficulty became so troublesome that he was confined to his bed. He had a sudden attack of pain in the lower abdomen, increase in temperature and pulse rate and collapse. He seemed to pass a fair amount of urine and catheterization was not done for fear of precipitating an attack of uræmia which was the tentative diagnosis. He died in 4 or 5 days before a positive diagnosis had been made. At autopsy a moderate degree of hypertrophy of the prostate together with three diverticula were found. One of the diverticula had ruptured because of a cancer which it contained. The diverticulum was situated along the posterior wall of the bladder.

Evidence of peridiverticulitis with resultant adhesions was present in every patient. The difficulty of removal in most instances made a careful examination of the diverticulum impossible. In three patients persistent post-operative fistula developed which did not heal for several months. Pyelonephritis was a complication in four; stone with pyonephrosis in one. In one instance only did the ureters open into the diverticula and the condition was bilateral.

Mortality. In the six cases in which resections were done there were no deaths. One of these patients died some weeks after leaving the hospital probably from acute renal infection. Two patients had drainage preparatory to resection; one of these died. One other had a carcinoma in an hour glass bladder and died after suprapubic drainage. In one case in which there were large stones in an enormously distended bladder with a diverticulum the patient died from the effects of suprapubic drainage. In six instances a diverticulum was discovered at autopsy; one of these patients had had a severe renal infection; one had had a few pus-cells in the urine; in the remaining cases there were no urinary findings. These patients did not have symptoms which could make a diagnosis of

Fig. 6 Shadow casting catheter carefully coiled in diverticulum the left lateral wall of the bladder

diverticulum probable except the one with renal infection. In the cases complicated by carcinoma, stones or severe renal infection, the mortality is high.

Post mortem findings. A review of the post mortem findings shows some interesting facts. Marked pyelonephritis was found in 80 per cent and was considered the major factor in causing death. A severe grade of nephritis was found in 78 per cent. In 55 per cent there had been severe cystitis and in two the inflammation in the diverticulum was more marked than that in the bladder. Two patients died of pneumonia.

CONCLUSIONS

1. The embryology of the bladder is not clear and in only a few cases does incomplete development account for the pathology. In some instances the condition may be congenital but other factors seem necessary before symptoms develop.

2. In this group the average age of onset (43+ years) would indicate that acquired factors (obstruction 86 per cent) seem necessary for the development of diverticula clinically.

3. Trauma was a factor in 22 per cent.

4. The cystogram and shadow catheter are of great aid in diagnosis and may be the only positive findings.

5. Surgery is the best method of treatment. The choice of operation depends on the location and size of the diverticulum.

6. When resection is possible the mortality is negative. In complicated cases the mortality is high because of renal and vesicle infection.

THE TREATMENT OF GENITAL TUBERCULOSIS IN THE MALE¹

By JOHN H. CUNNINGHAM, JR., M.D., F.A.C.S., BOSTON

THE material upon which this communication is based is from the post mortem and clinical data of the Boston City Hospital, the Long Island Hospital, where there is a large tubercular camp, private cases, and a survey of the literature.

Post mortem findings have been included first because examinations at autopsy are more accurate than clinical observation, and serve to establish the frequency of co-existing tubercular lesions in the different structures of the genital tract, second because it is frequently impossible to detect clinically the presence of tubercular lesions in the prostate and vesicles when tuberculosis of the epididymis is obvious, third because in tubercular epididymitis it is of great importance to know the probability of similar lesions in the other organs of the genital tract when they are apparently normal by every means of clinical examination, fourth it is of great value to know the frequency with which renal and vesical tuberculosis is to be expected together with tuberculosis of the epididymis, and fifth it is possible by post mortem examination to learn how frequently other organs, such as the lung, bone, etc., are tubercular also. Such information it seems to me must be the groundwork upon which our inaccurate clinical methods of observation stand, and it is from the actual knowledge or if not actual knowledge, the likelihood of the presence of the infection in the remainder of the tract that appropriate treatment should be based.

Autopsy findings. In 45 autopsies recorded I have been able to find 35 instances of *tuberculosis of the epididymis*, the most common lesion of the genital tract to be observed clinically, in which a microscopical examination as well as a gross description of the condition of the prostate and vesicles is recorded. Of these 35 cases the disease was bilateral in the epididymis in 15, and in 20 it was unilateral—right 12, left 8. In these 35 cases the vesicles were involved in 25, and the pros-

tate in 25. It is seen that in each instance where the vesicle was involved the prostate was involved also, and that there were 10 instances where the epididymis was the only structure of the tract affected, which gives good reason for the belief that the disease is usually primary in this organ. Of the 15 bilateral cases involvement of the seminal vesicles was bilateral in 11 and unilateral in 4. Of these 35 cases the testicle was involved in 19. In 4 of the cases involving the epididymis, vesicles, and prostate with a caseous tuberculosis there was an acute miliary tuberculosis of all the visceral organs which was the probable cause of death. In all of the other cases the primary cause of death was other than tuberculosis of the genital organ. In many of these instances of tuberculosis of the epididymis just mentioned the lesions in the prostate or vesicle were not, and in fact could not be detected by rectal palpation, because in some it was only on microscopical examination of the tissues that the lesion were detected.

Of these 35 cases the bladder was involved 16 times and the kidney showed unilateral tuberculosis in 11 and bilateral infection in 5. Tuberculosis of other structures occurred as follows: lung, 31; bone, 5; intestines, 8; ischio-rectal abscess, 3; some of the cases showing multiple lesions. In this series of 4250 autopsies there were two instances of caseous tuberculosis of the prostate without involvement of the vesicles or epididymis. In one there was no other focus of tuberculosis in the body, except in the lung, and in the other both kidneys and the bladder were tuberculous, and at the same time there was a lung focus.

Clinically. an analysis of the cases of tubercular epididymitis serves to substantiate the post mortem findings in some degree, but the discrepancies in demonstrating the high relative co-existence of the disease in the different organs of the whole tract, from the clinical data to follow must be attributed as previously stated to the inability to dem-

onstrate the lesions clinically as frequently as they exist.

Of 86 patients showing a tubercular epididymis, where the records are satisfactory, 41 showed palpable lesions on the vesicles and 49 in the prostate while 37 showed no palpable lesions in the vesicles or prostate.

In many of the instances where the vesicle and prostate were typically tubercular smears of the material expressed from them showed the tubercle bacillus in less than 15 per cent of the cases examined.

Of these 86 clinical cases the bladder and kidneys were examined in 51. The bladder was tubercular in 16, there was unilateral renal tuberculosis in 9 and bilateral in 5 and in 2 no renal tuberculosis could be demonstrated. In three cases there was a tuberculosis of the hip and 5 had Pott's disease, one had tuberculosis of the shoulder joint and 67 had distinct signs in the lungs.

A consideration of the literature both post mortem and clinical adds further evidence which lead one to the conclusion that tuberculosis of the genital tract in the male is most common in the epididymis where it is often primary occurring as a hematogenous infection and from the epididymis the disease extends along the vas, either by continuity or lymphatics to the vesicles and prostate. Walker in his remarkable monograph *Studies in the Experimental Production of Tuberculosis in the Genito-urinary Organs* states that secondary tuberculosis of the vesicles occurs in about 60 per cent of all the cases of genito-urinary tuberculosis and as shown in my post mortem findings when the vesicles were involved the prostate was involved also (25 out of 35 cases).

There is much evidence to support this view. Simmonds found in a series of 35 cases of genital tuberculosis that the vesicles were infected in 29 and the prostate in 26. Oppenheim in a series of 27 cases found the vesicles invaded in 17 and the prostate in 18. Krzywicki in a series of 15 cases showed the vesicles tubercular in 11 and the prostate in 14. Collinet in a series of 70 cases found the vesicles involved in 36 and the prostate in 44. Saxtorph, in a series of 547 instances of genital tuberculosis found at autopsy records

but two instances where the only demonstrable lesion was in the vesicles and 9 cases where the only lesion was in the prostate. Teutschlaender in a series of 57 cases found but a single example of tuberculosis confined to the vesicles. Guys in a series of 183 cases of genital tuberculosis found 10 involving the prostate and vesicles alone. Socin and Burchardt record 44 clinical cases of genito-urinary tuberculosis and found no instance where but single structure was involved.

The question of whether tuberculosis occurs as a primary lesion in the prostate or vesicles as far as the genital tract is concerned is of only passing interest. As regards the prostate it must be considered extremely rare but an autopsy record by Crandon and two by Krzywicki and the two cases in my series show that the prostate may rarely be the only organ of the genital tract to be infected. In regard to the vesicles the autopsy findings of Saxtorph, Teutschlaender, Oppenheim, Orth, Dreyer and others must lead to the belief that this structure may be the only one of the tract to harbor tuberculosis yet the vesicles, like the prostate are usually infected from a tubercular process in the epididymis or kidney. From this evidence it is not to be presumed that when the vesicles give clinical signs of a tubercular process, these structures are the only part of the genito-urinary tract involved.

It may be safely concluded therefore from the post mortem and clinical data that when tuberculosis is present in the epididymis there are tubercular lesions in the vesicles and prostate in most instances whether they can be demonstrated clinically or not.

Treatment. It is upon this well founded assumption that treatment should be based. There are those who recognizing lesions in all the different organs of the tract recommend and have practiced a total removal of the genital tract. On the other hand there are those who recognizing the same condition advocate no surgical procedure but rely on general hygienic measures, symptomatic treatment and tuberculin. Between these two extreme points of view we have

those who advise simple drainage of tubercular abscess or removal of the scrotal lesion either by epididymectomy or castration leaving the disease in the vesicles and prostate kidney and bladder as the case may be to be taken care of by reliance upon the improvement in general condition after the removal of the scrotal focus followed by employing hygiene tuberculin or both to immunize the individual against further outbreaks of the disease. As has been pointed out tuberculosis of the upper urinary tract may be associated with the genital tuberculosis in some instances and a knowledge of the condition of the bladder and kidneys should be ascertained if possible by cystoscopy ureter catheterization and renal function tests before the method of treatment should be decided upon and if a complete examination of the upper urinary tract is impossible at least a catheter specimen should be subjected to urinalysis and bacteriological study. It is obvious that a complete knowledge of the individual case is of value in prognosis and must influence the course of procedure in the treatment. Naturally a patient with tuberculosis of the whole genito-urinary tract or advanced phthisis should not be treated surgically except in a palliative way.

Before proceeding to elective surgical operations upon the genitals it is essential to have besides a complete knowledge of the genito-urinary system the evidence furnished by a general physical examination for it has been shown that tuberculosis of the urogenital system is always to be considered secondary to a tubercular process elsewhere in the body. It is only upon a complete knowledge of the individual case that appropriate treatment can be instituted.

It must be clear that the problem of treatment must be considered as one of immunization for with the presence of tubercular foci in different organs of separate system of the body no surgical procedure can entirely free the patient of the disease as such. All evidence in regard to the surgical treatment of tuberculosis points to but one conclusion namely that surgical treatment does not in itself fulfill all the indications and

localized tuberculosis in the genital system as elsewhere should therefore not be considered as a purely surgical problem but rather that surgery may be a valuable method of freeing the bodies of accessible foci that the natural immunizing function of the body may be improved and other immunizing measures may be more effective.

In regard to what may be expected from surgery as applied to genital tuberculosis there is no report as complete as that by Barney. He has shown from a study of 154 cases of genital tuberculosis at the Massachusetts General Hospital that tuberculosis was demonstrated clinically in other part of the body in 55.8 per cent of the cases (lungs 35 cases kidney 7 cases bones 7 cases). Of these 154 patients he was able to trace 113 and found that 31 died of tuberculosis and 8 from other causes. Of the 31 patients dying of tuberculosis 15 developed signs of tuberculosis elsewhere in the body following operation. Of these 31 cases 4 or 14.2 per cent died in the hospital within a month after operation 9 or 32.1 per cent died within 6 months and that within one year 50 per cent had died. At a period of six years after operation 8 per cent had died.

The results obtained by the attempt to remove the whole genital tract are not at hand except those of Whiteside's who in 1914 reported 22 cases of removal of the whole or one half of the genital tract that is the testicle with the epididymis the vas seminal vesicles and prostate. In that series he considered 4 cured 9 died or phthisis (time after operation not stated) 3 died within a few months from local infection 6 were lost sight of presumably they may be dead. There was no operative mortality. The time required to do the operation was about three hours.

Personally I have recognized the advantages of a total extirpation of the genital tract in suitable cases because of the associated tubercular lesions in other parts of the genital system yet the technical difficulties entailed in performing this operation several times upon the cadaver have kept me from employing it in the living.

The most complete report of cases followed

for many years, that I can find is by Haas. He records the results of the Tuebingen clinic of Bruns, which follows 111 patients, upon whom either single or double castration had been performed were examined at periods subsequent to the operations varying from three to thirty years. In 78 of the cases one testicle, and in 33 of them both testicles were removed. The vas was divided high up in all cases. In 26 per cent only of the unilateral castrations did the disease appear in the other testicle later but 9 per cent of the same patients died of tuberculosis of the urinary tract. Most of the latter number had shown evidence of tuberculous disease of other parts of the tract previous to the operations. Cure followed the unilateral castrations in 44.6 per cent of the cases. Of the 33 patients who were submitted to double castration 56 per cent were cured, 15.6 per cent died within the first three years after ward from genito-urinary tuberculosis in some form or other. The mortality therefore, of complete castration within the first three years after the operation was nearly twice as great as that seen in connection with the unilateral operation in the same period but, on the other hand, the percentage of cures among the patients upon whom complete castration had been performed and who survived more than three years after ward, was noticeably greater.

The procedure of removing the scrotal focus, either by epididymectomy or castration with subsequent hygienic treatment, and in recent years by employing tuberculin is today the most common practice. Barney's report, the most recent and complete in regard to end results, showing a mortality of 85 per cent within six years following such procedures in an institution of the highest surgical efficiency is far from satisfactory.

There is much evidence in support of the benefit which may be expected by the employment of hygiene and tuberculin. I have recently examined several cases who have been under the care of Dr. George Sanborn, director of the Department of Vaccine and Serum Therapy at the Boston City Hospital. I am convinced that much benefit has resulted in the cases which have been treated

by tuberculin subsequent to the removal of local genital foci and there are two cases with which I have been personally familiar that from all objective and subjective signs may be considered free from tuberculosis in the genito-urinary tract without any previous surgical procedures. One is a young man seen in 1907 by Dr. John T. Bottomley. A diagnosis of tuberculosis of the right kidney was made by ureter catheterization and inoculation tests, and there was a characteristic unilateral genital tuberculosis. An abscess developed in the scrotum from which the tubercle bacillus was isolated. After 18 months treatment by tuberculin the symptoms were entirely absent and two years ago 1914 inoculation tests of the urine were negative.

Another case a man 24 years old had a unilateral genital tuberculosis resulting in abscess formation in the scrotum. After 6 months treatment with tuberculin the wounds were healed and there were no subjective symptoms. This patient was seen on March 26 1916. The testicle and epididymis were practically destroyed leaving a small fibrous body. There was a hard nodule in the left lobe of the prostate and the left vesicles had somewhat thickened walls but not enlarged. The material expressed was not abnormal and inoculation tests of the urine were negative, and no organisms could be found in smears. There are many other cases who have received the same sort of treatment in which the results are not so brilliant, yet I am convinced that this form of treatment is a great adjunct to surgical measures and should form the after treatment in all operative cases and the chief feature in non-operative cases.

Being convinced of the greater advantages to be gained by eliminating the disease from the structures in the genital tract above the epididymis, and yet being fearful of a radical surgical procedure which attempts to wholly eradicate the disease because of the difficulties dangers and failures, I have chosen to attempt to remove the disease from the vas, vesicles, and possibly the prostate by performing epididymectomy or castration infecting the vas with crude carbolio acid and later employing hygiene and tuberculin. The

idea of this form of treatment was suggested by Belfield's paper entitled Irrigation and Drainage of the Seminal Ducts and Vesicles Through the Vas Deferens in which he advocated treatment of the infected vesicles by injections through the vas deferens and from the results of the treatment of the tubercular ureter by the injection of carbolic acid following nephrectomy as practiced at the Mayo Clinic.

The number of cases subjected to this method of treatment in which the results are known is 32. In 14 lesions of the epididymis alone could be demonstrated prior to operation. In 18 lesions of the vesicles were present and in 15 lesions of the vesicles and prostate also were evident. In 5 patients the lesions in the epididymis were bilateral. Three patients had tuberculosis of the bladder and unilateral renal tuberculosis. No cases with bilateral renal tuberculosis were subjected to epididymectomy or castration and are not considered in this report. Twenty-three had phthisis and 2 had tuberculosis of the bone. Thirteen were subjected to unilateral epididymectomy, 2 to bilateral epididymectomy, 1 epididymectomy on one side and castration on the other, 14 were subjected to unilateral castration because the disease involved the testicle and 2 bilateral castration. 3 had a subsequent epididymectomy for recurrent disease and 4 had a subsequent castration for recurrent disease, 1 had a subsequent nephrectomy and 2 had previously had a nephrectomy for tuberculosis. I have previously mentioned a case of tubercular epididymitis on one side and a gonorrhoeal epididymitis on the other. The tubercular epididymis which was removed showed both a tubercular and gonorrhoeal infection. Of these 32 patients 7 are known to have died. The following table shows deaths by year and causes.

Year	Post-operative	Number of cases	Per Cent	Remark
1914	0 to 6 months	1	1	Nervous breakdown Suicide
1915	0 to 6 months	1	1	Post-operative nephritis
1916	6 to 12 months	1	1	Phthisis-cultured tuberculosis

1999	504 to 510 months	1	1	Phthisis-urine neg. tv
2000	510 to 516 months	1	1	Phthisis-urine neg. tv

Of this series of 32 patients the urine has recently been studied in 25 these being alive at the present time and no evidence of genital tuberculosis is to be found in 21. One has tubercular lesions in the bladder and prostate five years after unilateral castration and is one of the cases in which a nephrectomy was done. One has bilateral renal tuberculosis 7 years after operation and two have tubercular lesions in the prostate and possibly the vesicles one four years and one three years after operation. Of the remaining 21 cases there is no evidence of the disease in the local examination the urine is negative and smears of the massage fluid from the prostate and vesicles is negative in each instance. In but one patient was the inoculation of urine into guinea pigs positive and this case had a right castration in December 1914 and a left February 1915. The urine is negative by urinalysis and the smears negative. This patient is in excellent health and the inoculation findings were a surprise.

To summarize: Of these 32 cases 7 or 21.7 per cent have died in 10 years 25 or 88.3 per cent are living, 4 have demonstrable tuberculosis in the genito-urinary tract, 1 has no demonstrable tuberculosis but the inoculation test is positive, 20 or 62.5 per cent are locally free from the disease.

The operative technique is briefly as follows. The patient comes to the operation with at least one hour's urine in the bladder or if the bladder is empty about 4 ounces of water is injected. After performing epididymectomy or castration the vas is injected with a drachm of crude carbolic acid by means of a syringe fitted with a metal tip usually employed to make injections into a ureter catheter. The vas is brought to the surface of the skin through a stab wound above the scrotum and held by a catgut suture the lumen being unobstructed. The scrotal wound is closed with or without drainage as the case may indicate and an alcohol dressing applied to neutralize any of the carbolic acid which may escape. The urethra is washed out to remove any carbolic acid which may have escaped into it but as a rule the acid runs back into the bladder and is diluted by the bladder fluid.

Upon recovering from the operation the patient usually voids early as the irritation from the carbolic acid is evident, and because the bladder contains fluid at the time of operation. In a few instances the patients have required catheterization.

Pain during the first few days after operation is often considerable requiring liberal doses of morphia yet some patients have had little or no pain. In a few micturition has been so frequent and painful that an indwelling catheter has been necessary and several patients have passed blood in small amounts, mixed with the urine for a few days to a fortnight. There is rarely "vesicle colic" and rectal irritation, and the urine may contain much detritus for many weeks. There has been no evidence of carbolic acid poisoning.

The reaction from this method of treatment, while severe in some cases, is slight or absent in others and whatever immediate discomfort there may be is of only passing interest if we can free the genital tract of so severe a disease.

The examination of the vesicles and prostate months following operation usually shows the vesicles to be small fibrous bodies if palpable at all and the prostate sometimes quite normal but often sclerotic and the material expressed by massage is small in amount. In no instance has the massage fluid following operation shown the tubercle bacillus in smears, and in no instance has a contracture taken place in the urethral canal.

Following the healing of the wound and the subsidence of any febrile state the patients have been given tuberculin, the dose being at first small and gradually increased. The general hygienic measures, commonly employed in tuberculosis, are insisted upon and carried out indefinitely.

CONCLUSION

1. The post mortem and clinical findings show that the great majority of cases of genital tuberculosis have active tuberculosis elsewhere in the body the infection in the genito-urinary tuberculosis being a secondary infection

2. It must be considered that the majority of cases of tubercular epididymitis have tuberculosis of the vesicles and prostate on the corresponding side, whether the condition can be demonstrable by physical examination or not.

3. Cases of genital tuberculosis often have associated tuberculosis of the bladder and kidney and a cystoscopic examination with catheterization of the ureter should be a routine procedure in each case before the possibility of such associated infection can be eliminated.

4. In the opinion of the writer the best treatment for the local condition in most instances, is to remove the scrotal focus by epididymectomy or castration, and this should be followed by injecting the vas with a drachm of crude carbolic acid, with the hope of eradication of the disease from the genital tract.

5. That the destruction of the local focus by this procedure is but the first step in the process of immunizing the patient against fresh outbreaks of the disease and that hygienic and tuberculin should be made use of indefinitely as they serve further to aid, in a rational way the immunizing power of the body against remaining lesions.

THE TREATMENT OF THE FATTY CAPSULE AND THE URETER IN NEPHRECTOMY FOR RENAL TUBERCULOSIS

By HERMAN LOUIS KRETSCHMER, M.D., F.A.C.S., CHICAGO

Urologist, Presbyterian Hospital, Genito-Urinary Surgeon, Mount Zion Hospital, Junior Surgeon, Child Memorial Hospital

IN a consideration of the surgical treatment of renal tuberculosis two facts stand out prominently (1) the present status of the question relative to the diagnosis and treatment of renal tuberculosis (2) the fact that the management of the fatty capsule and the ureter has not been a definitely settled as has the former.

With reference to the first topic I should like to refer to Cabot's introduction to a recent article on this subject in which I think he sums up the question of diagnosis and treatment as well as it can be. Though many points connected with the diagnosis and treatment of renal tuberculosis have been practically settled during the past ten years much still remains to be done. In expert hands the questions of diagnosis have been well cleared up and the formerly much discussed question of the advisability of surgical treatment has ceased to play an important part. The tendency to watchful waiting which was generally but another name for medical procrastination has considerably abated and there is practically no difference of opinion among those qualified to express one that in unilateral renal tuberculosis

operation offers the only chance of cure and the so-called medical treatment only prolongs the agony.

When however our attention is directed to a consideration of the management of the fatty capsule and the ureter in nephrectomy for renal tuberculosis one finds a great many different expressions of opinions somewhat analogous to the unsettled and chaotic condition which the entire question of surgery of kidney tuberculosis was in ten years ago. Because of these facts one is justified in stating that the question of treatment of these two structures is not as definitely settled as are the questions of diagnosis and treatment.

Until comparatively recently the fatty capsule has been either ignored or sadly neglected. Many of our standard textbooks do not refer to it at all. Just why it should have been overlooked is not clear. Many of the more recent writers attribute to it the possibility of its being one of the causes of post-operative sinus formation after nephrectomy and that not all of the post-operative fistule or sinuses are due to the ureteral stump. A consideration of the fatty capsule as a factor in the production of fistule

or of an infection of the wound by tuberculosis cannot be undertaken without reference to the lymphatics.

The most extensive work on the lymphatics of the kidney and its capsule has been done by Stahr. He has shown that there are two capillary networks within the fatty capsule of the kidney. A coarser network which lies under the peritoneum, superficially in the fatty capsule. A second capillary network lies in the deeper layers of the fatty capsule close to the kidney substance. This is a delicate network and according to Stahr is in direct communication with the lymph capillaries of the kidney cortex. By injection preparations he was able to demonstrate that the kidney possesses a rich network of lymphatics. *The different lymphatics leave the kidney at the hilus but in spite of this he has demonstrated that a lymphatic connection exists between the lymphatics of the kidney and its capsules.*

These anatomic facts are of much importance in a consideration of the treatment of the fatty capsule. If we accept Stahr's work as having proved that this lymphatic connection exists, then it is reasonable to expect that in all, or in the largest majority of cases, the fatty capsule must sooner or later become infected. The possibility of the fatty capsule becoming infected in each case naturally brings up the question of whether or not it is proper to remove it as a routine in every case.

Clinical evidence of involvement of the fatty capsule is seen in some of the late cases in which at the time of operation the fatty capsule can be recognized as being definitely pathological. Schlaginweit, in one of his cases found a pathologically altered and enlarged lymph-node about the size of an almond, in the fatty capsule.

Legueu maintains that the fatty capsule is almost always changed, indurated and more or less adherent to the kidney. Sometimes the lesions are purely inflammatory but they are generally tuberculous, and many authors have demonstrated specific lesions in them (Israel Albarran, Pousson Kapsammer Kidd).

Tuberculosis of the fatty capsule may be evident in cases where tuberculous granula-

tions are seen on the surface of the kidney. Not only are tuberculous changes found in cases in which the fatty capsule appears altered to the naked eye but they have also been found in cases in which the fatty capsule appeared perfectly normal. Legueu has demonstrated microscopic tubercles in the perirenal fat, in pieces of the fatty capsule taken at random from areas that appeared normal to the naked eye.

These facts would appear to be rather conclusive evidence in favor of a removal of the perirenal fat, or as much of it as possible in cases of nephrectomy for tuberculosis. Albarran believed that the course of the disease was shortened by secondary removal of the fatty capsule. However Schlaginweit, holds opposite views in his first nine or ten nephrectomies he removed the fatty capsule with a great deal of trouble and loss of time but since then he has left it in place. He believes that if the fatty capsule is normal soft, and does not contain any palpable glands it does not do any harm. If it is hard and rigid, it has formed a protective wall before the operation and will continue to do so afterward. Recommendations to remove the fatty capsule have been made by Kuester Koenig and Pels Leodsen Kidd Wildholz Kelly Watson and Cunningham, and others.

During the past three years I have made it a routine procedure to remove as much of the fatty capsule as possible. This was carried out after the kidney was removed. In cases in which there has been a good deal of perinephritis, with extensive thickening of the fatty capsule so that extensive adhesions are present, rendering the removal dangerous it may be necessary to forego its removal. The danger of injury to the peritoneum with resulting tuberculous peritonitis is obvious.

THE TREATMENT OF THE URETERAL STUMP

The management of the ureter has caused more discussion than perhaps any other phase of the subject, and it is the one which up to the present time has not been satisfactorily settled to all concerned. The many different ways of treating the ureter which have been advised is proof that the ideal method has not been obtained.

When nephrectomy was first recommended it was also advised to remove more or less completely the diseased ureter. The more recent train of thought seems to be to remove only a part of the ureter as much as can be conveniently removed through the lumbar incision which usually means to the brim of the pelvis.

Total extirpation of the ureter to the bladder or to include a piece of the bladder was not a very long lived procedure. These procedures were recommended by Alessandri, Garceau, Giorgano, Ramsey, Goetzel, Kelly, Reynolds, Israel, Kapsammer and others. This method soon fell into disfavor because it did not fulfill its claims because of the increased mortality rate and because it did not prevent post-operative fistulae. Although the present-day tendency is not to do extensive resections, Longard has described a new technique which has for its object the removal of as much of the ureter as possible.

The kidney is exposed by the usual lumbar incision, after the vessels have been ligated and the kidney freed, the ureter is freed down to the pelvis and a second incision is made parallel and close to Poupart's ligament. The incision is carried through the muscles to the peritoneum, the kidney and the attached ureter are pulled through this incision, after which the ureter is divided and fixed into the wound. In large kidneys or where there is danger of rupturing large pus-sacs, he divides the ureter in the kidney wound, covers the end with gauze and then pulls it through the lower incision with a forceps. His method slightly modified has been advocated by Lillienthal.

Suture of the ureter to the skin. This method was advised in order that the ureteral mucosa could be treated directly and to prevent infection of the wound with tuberculosis and fistula formation. Israel in his analysis of 1023 cases obtained figures showing that fistulae occurred in 10 per cent of cases in which the ureter was allowed to drop back into the wound whereas sewing the ureter into the wound was followed by fistulae in 16.3 per cent of cases.

Treatment of the ureteral mucosa has been varied. Kuemmell uses a special thermo-

cautery which is introduced into the ureter and Albarran, Tufner and others sear it with heat. Electrolysis has been advised. Israel prefers the injections of pure fluid carbolic acid into the lumen of the ureter, filling up the entire ureter and Koenig injects tincture of iodine. In order to bring about an early healing, Taschkis advises that the stump be given antituberculous treatment after the operation. Zuckerkandl recommends 6 per cent carbolic acid. The mucosa near the end of the ureter has been removed with a curette. Comment on these varied recommendations is unnecessary.

METHODS OF SEVERING THE URETER

These have been varied. The end of the ureter may be crushed with a heavy forceps and cauterized with carbolic or iodine. Others prefer to burn through the ureter very slowly with the actual cautery.

Invagination of the cut end of the ureter by a purse string somewhat similar to the technique in appendectomy has been suggested in order to insure a more thorough closure of the cut end either with preliminary crushing of the ureter or with ligating. Ligation and invagination have been criticised because the end containing the ligature lies in the lumen of the ureter. This method has been advocated by Koenig, Kuester, Pels, Leusden, Krecke, Jansen and others.

That occasionally special treatment is not necessary is demonstrated by Schlaginweit. In several cases the ureter was simply cut off and allowed to retract. The cases ran a usual post-operative course. Taddei has shown by experiments that the ureter closed quicker when it was not ligated. When it was ligated, hollow spaces formed in the walls resembling true cysts. There was never a trace of reflux of urine into the wound. The ureter atrophied quicker when no ligature was applied, therefore in non-septic conditions he advises against ligation of the ureter. One would not feel justified, however, to apply the results of Taddei's animal experiments in his own clinical cases.

At the present time, based upon past experience and results by far the largest number of surgeons are practicing less radical

measures than formerly so that only a partial ureterectomy is carried out.

I have never attempted extensive resections of the ureter being content to remove as much of the ureter as I could through the lumbar wound. Usually I was able to divide the ureter at the pelvic brim, and occasionally just below it. The ureter was divided between heavy artery forceps. The cut end was treated with carbolic acid and tied with heavy catgut, and allowed to drop back into the wound. The objection to leaving a stump of the ureter has been that it continues to pour infectious material into the bladder thereby infecting a clean bladder or delaying the healing of an already infected bladder. Who can say that a long stump is any more infectious than a short one?

Albarran Kuester Koenig and Pels-Luesden Suter Mayo Legueu, Cabot, Squier Borelius, Kidd, and others are all doing partial ureterectomies. Post mortem examinations of the stump after nephrectomy have shown that the ureter has undergone atrophy and been converted into a hard, fibrous cord.

Attempts have been made to modify the technique according to the pathological condition of the preter. Some believing that the technique should be based upon the condition of the ureter as found at the time of operation. As a rule however the condition of the ureter has not been taken into serious consideration.

Albarran's decision whether a conservative or radical ureterectomy should be carried out, is reached upon the ureteral findings. If the thickened ureter is increased in circumference because of a thickening of its walls and if its lumen is small he proceeds as usual in that he resects as much as can easily be resected and these cases heal without fistulae formation. If the ureter is very thick, and the lumen on cross section is dilated then and only then should ureterectomy be carried out as completely as possible. In these cases the vesical end of the ureter is dilated and altered. This is the type he believes, in which the bladder urine flows up the ureter and into the lumbar wound.

THE INFLUENCE OF EARLY DIAGNOSIS

Tuberculosis of the kidney is no exception to the rule that an early diagnosis is by far better than a late one. From personal observation I believe that cases in which an early diagnosis is made and in whom an early operation is performed have less bladder disturbance after the operation, and that bladder symptoms persist for a much shorter time than they do in those patients who come to us late in the course of the disease.

At rare intervals one may see a case in which there is no evidence of bladder or ureteral tuberculosis cystoscopically. This group of cases undoubtedly have a much better end result than do those in whom at the time of operation an extensive tuberculosis of the bladder exists.

By many these facts are held responsible for fewer ureteral fistulae and hence a shorter period of wound healing. One must not forget, however that in renal tuberculosis involvement of the ureter occurs quite early.

While many authors believe that fewer post-operative fistulae and a shorter wound healing are directly due to an early diagnosis and early operation, these views are not held by all. Some believe that post-operative fistulae are not due to any particular type of ureteral tuberculosis but to a better operative technique, rigid asepsis and a more careful division of the ureter.

PRIMARY CLOSURE

The formation or occurrence of post-operative fistulae and infection of the wound by tuberculosis has resulted in the various methods of treatment of the ureteral stump and the fatty capsule. The objects of these methods however were not attained. This failure was quite common so that some (Oppel, Stein) did not try to obtain primary wound healing. Instead they packed the wound with gauze and allowed it to heal by granulation.

This technique must of necessity prolong the convalescence and as a routine procedure can hardly be recommended, except in an occasional case in which the wound may have been contaminated by pus due to rupture of one of the thin walled sacs.

Quite the opposite treatment has been advocated by Mayo who advises against drainage. In cases in which the wound is soiled by infected material this is wiped out, the cavity filled with normal salt solution and the wound closed without drainage. If this method succeeds it will add greatly toward shortening the convalescence.

Cabot and Crabtree's interesting study of their cases closed without drainage show that only 25 per cent remained tight. Another fact of much significance brought out in their paper is that in their cases in which an abscess developed it occurred in three to five weeks after the patients left the hospital. This fact is especially significant when reporting cases

of primary closure unless the cases are watched after leaving the hospital one might easily come to wrong conclusions.

REGURGITATION OF URINE

Regurgitation of urine into the remaining ureteral stump and its discharge through the lumbar wound may be the cause of a persistent sinus. Tuberculosis of the ureter often results in a destruction of the ureterovesical valve so that there is nothing to prevent the flow of urine through the lumbar wound. This complication however is rare. I have seen it but once. One might be guided in his attempts to prevent this complication by the cystoscopic findings.

THE CLINICAL AND PATHOLOGICAL EVIDENCES OF THE POSSIBILITIES OF SPONTANEOUS HEALING OF RENAL TUBERCULOSIS WITHOUT TOTAL DESTRUCTION OF THE KIDNEY¹

By EDWARD L. YOUNG, JR., M.D., Boston
Genito-Urinary Surgeon, Out Patient Department, Massachusetts General Hospital

IN any discussion involving a number of terms which may be used with varying shades of meaning it is only fair that a complete understanding of what we mean by our use of words should be made plain that no doubt or question should arise later.

As evidence of renal tuberculosis we must have tubercle bacilli and evidence of renal inflammation coming from the kidney. It is not enough that these elements come from a bladder urine since genital tuberculosis in either sex coming from the epididymus or the prostate in the male or from the fallopian tubes in the female give such a urinary content it is not enough that the bacilli be found in the urine when obtained direct from the kidney if there is no other evidence of kidney involvement since it has been proved beyond doubt that normal kidneys excrete living tubercle bacilli coming to them in the blood from other tuberculous foci in the body. And in as much as no one will deny the possibility of small active tuberculous foci in the body

which are undiscoverable on physical examination bacilli alone in the urine cannot be accepted as evidence of renal involvement.

By healing we mean a complete destruction of a tuberculous focus so that no living tubercle bacilli remain. It is not enough that a caseous area is completely surrounded by a wall of fibrous tissue however dense so long as the center is not completely organized. Kurlow and Green by use of the microscope and guinea pig inoculation proved conclusively that as long as caseation existed there remained the possibility of further infection. It is true that under the best of artificial conditions a strain of tubercle bacilli will die in a comparatively few weeks but these are not and cannot be the conditions existing in the body and at present we have no means of knowing how long tubercle bacilli in a caseous mass can retain their vitality and power of doing harm. By healing then we mean the destruction of all of the tubercle bacilli and the reduction of the caseous nodule to a harmless condition.

By spontaneous healing we mean not only without any treatment at all but by the use of any treatment outside of the knife.

What can we accept as a sufficient proof of a healed renal tuberculosis? Nothing less than the operative or autopsy evidence of what we know is a characteristic organized tubercle or collection of tubercles taken from the kidney of an individual who showed during life tubercle bacilli and evidence of renal inflammation coming from that kidney.

Clinically there have been many reports of cases of renal tuberculosis where the diagnosis was certain and where either without any treatment or because of or coincident with the use of some special therapeutic agent the clinical signs and symptoms entirely disappeared and pus and albumin and tubercle bacilli could no longer be found in the urine and the vesical symptoms of irritability ceased and the patient gained in weight and general condition.

Pardoe reported 21 cases in which 5 appeared to be cured by the use of tuberculin in very early cases where there was little if any bladder involvement. But recognizing the possibility of long remissions in the signs and symptoms he did not consider proof of the cure at all complete.

Thompson Walker also considered the use of tuberculin as likely to give freedom from symptoms for a long time but did not believe that a cure ever resulted.

Keyes reported three cases before this association in which there was a remission of from 2 to 17 years. In the case with remission for the longest time the diseased kidney was entirely destroyed as proved at autopsy. In the other two there was a flare up of the disease and nephrectomy was done.

Hertz Boyer reports one case in which there was no suspicion of tuberculosis in the history physical examination, or cystoscopy. Re-examination two months later showed a closed left kidney which had not been diagnosed on the first examination. A few months later the patient died of uremia.

He cites another case in which a patient was supposed to have been cured of renal tuberculosis, but twelve years later had a swelling in her loin which did not interfere

with her general health and activities so that she did not consult with a physician for eight years more. A nephrectomy done at that time showed a totally destroyed caseous kidney.

Mantoux advocated the use of tuberculin in renal tuberculosis and claimed that the general health was much improved and also that the local condition was changed for the better and although among seventy cases which he observed some were at one time or other almost free from symptoms, he nevertheless did not claim a cure by means of medical treatment and insisted that operation gave the only chance.

Le Clerc Dandoy adopted Keersmaecker's method of administering tuberculin treatment which consists in giving intravenous injections of cinnamyl acid every week, increasing the dose up to 20 mg. At the end of six months this is stopped and the tuberculin is given in slowly ascending doses. He reports five cases in which a diagnosis of renal tuberculosis was made and in which after several months treatment by the mixed method the symptoms entirely cleared up and the urine became entirely normal. Two of the five cases give all of the symptoms necessary to make a diagnosis, but the final proof of cure is lacking.

Pousson has reported one case with remission of symptoms for eighteen years and then further trouble and he has become reluctantly convinced that renal tuberculosis cannot be cured except by removing the kidney.

None of the reported cases on close examination fulfil all of the requirements necessary to establish definitely the proof of a cure and many of them do not have all of the data possible to obtain during life. The cases reported by Keyes showed at one time all of the clinical phenomena consistent with a cure and had the final flare ups not been reported would have been used as evidence of a cure instead of standing as they do as strong arguments against. In the literature on renal tuberculosis I have not been able to find any case reported which shows positive proof of the disappearance of a renal tuberculosis.

The following reports of cases studied on the Genito-Urinary Service at the Massachusetts General Hospital are of considerable interest in this connection

G U Service No 03058 Female age 31

Symptoms of intermittent pain in left side for three months no other symptoms and well up to that time. The urine showed a moderate number of leucocytes no albumin, no growth on culture but a diphtheroid bacillus in smear Cystoscopy showed that the leucocytes came from the left kidney. Operation by Dr Cabot showed that the upper pole contained a cyst shut off from the pelvis of the kidney. The upper pole was resected under the impression that it was a solitary cyst no suspicion of its nature being entertained. Normal convalescence. The diagnosis was only revealed by the pathologist.

G U Service No 20473 Female age 48

Four months symptoms of chills fever and weakness slowly increasing with an ache in the left flank. The examination was typical of a coccus infection of the left kidney with perinephritic abscess. Operation showed this condition and because the kidney was badly damaged it was removed. Pathological examination showed the coccus infection but in the upper pole was a small caseous cavity partly organized which was tuberculous.

G U Service No 180035 Female age 54

Five years ago urgency and frequency and three years ago tumor in left flank. Nephrotomy was done at this time. Sinus persisted and two years ago an attempt was made to cure this by operation without success. Nephrectomy was done.

Pathological report. Section showed no kidney substance. A number of small abscesses filled with thick pus but a large amount of the tissue consists of soft yellowish material. Microscopical examination shows the kidney tissue replaced by a round and epithelioid cell growth throughout which were masses of large scattered giant cells.

In these cases there was a shut off tuberculous process which it was impossible to diagnose as such without microscopic study but in one no evidence at all of any attempt at healing in one only a slight attempt while in the third a considerable degree had gone on, yet in no sense of the word to completion.

Pathological evidence at our command is unfavorable to the possibility of the healing of tuberculosis of the kidney. Wherever tubercle bacilli lodge and start to develop they arouse a reaction which is essentially the same under all conditions the particular tissue invaded causing only minor differences. The process of growth and attempt of the tissue at walling off and healing the damage is likewise essentially the same. Histologically the process is in brief as follows. The pres-

ence of the bacilli is the signal for an accumulation of endothelial cells around them in an attempt to neutralize in some way the damage being done. These endothelial cells together with lymphocytes and new connective tissue cells gradually get more numerous and the shutting off of the blood supply begins in the center of the tubercle. If healing is to take place the newly formed connective tissue cells grow into this necrotic center and gradually absorb and take the place of it. There may be a hyaline degeneration of this ingrowth but the round cell infiltration and the more or less characteristic center always remain to mark the spot. In the larger tubercles the caseous center may be replaced by a calcification surrounded by a dense fibrous wall. This picture is characteristic and can be distinguished from the scars in the kidneys of various origin which masquerade in the literature as healed tubercles. Both types are found in the foci of healed or obsolete tuberculosis elsewhere in the body. That this is the natural process which should take place in the kidneys we know from a few reported cases where such an attempt has been made but without success.

Harbitz reports a number of autopsy and post-operative cases where the tuberculous process had disappeared after complete destruction (autonephrectomy) of the kidney but one case of particular interest.

A woman age 33 with symptoms of right-sided kidney trouble for two years. Tuberculosis could not be found. Nephrotomy showed nothing wrong but the wound left a permanent sinus. Three months later nephrectomy. Macroscopically no evidence of tuberculosis, but microscopically there are typical tubercles some of which have gone on to almost complete organization but some of which still are active.

Wildbolz recognizing that a marked improvement in general condition followed the use of tuberculin in many cases thought that a corresponding healing might take place in the infected kidney. In four cases he used tuberculin for 2 to 12 months before operation with improvement in general health and with some benefit as regards symptoms. He did a nephrectomy in all of these cases and examined the kidneys care-

fully to see what, if any healing had taken place. Nowhere was he able to find any evidence of any process which suggested an attempt at healing. He concluded that although medical treatment might improve the general condition of a patient with renal tuberculosis it did not in the least help the local lesion and that removal of the kidney was the only permanent cure.

Zuckerlandl in discussing the possibility of the shut off tuberculous pyonephrosis also describes the indurated tuberculous kidney where the tissue reaction has resulted in a partial healing of many of the foci with a marked fibrous tissue reaction around the tubercles and a sclerotic condition of the whole kidney with a thinning of the cortex and a hardening of the parenchyma. In one case which he describes there was also a fatty infiltration of the tissue near the pelvis. But in all of the cases there were demonstrated one or more small active foci. It is to be noted that this process is destructive of the kidney and not healing. Zuckerlandl concludes that induration of a tuberculous kidney and hardening of the parenchyma may be taken as a local recovery but never absolute. (One might suggest that this type of healing is not of advantage to the kidney.) The diseased kidney even after complete induration is always a present menace to the other kidney and its removal is urgently recommended.

Reasoning from still another point of view suggests that healing should be a difficult if not an impossible task. Immunity is aroused very slowly in the body by a focus of tuberculosis anywhere. In the lungs where the anatomy is such that the growth may be very slow in extension and yet the blood supply so abundant that the toxins are rapidly absorbed and disseminated and the greatest opportunity given for antibodies to be formed such an immunity is often aroused and the process limited, walled off and finally healed before it has become too large to handle. In the kidneys the conditions are slightly different in that extension takes place more rapidly and the antibodies are formed less quickly. By the time these antibodies have been formed to any great extent the focus

is so large that the most that can be accomplished is the walling off of the process without complete healing. Whether this is the exact explanation or not really matters little but I am convinced that the question of immunity is the real answer to the problem. In reviewing the course of the patients on whom nephrectomy for tuberculosis had been done at the Massachusetts General Hospital Crabtree and Cabot found that the cases which had done the worst were the early cases those in other words who had not had time to arouse an immunity. Other reports from other clinics revealed the same thing.

I had one experience of this kind which illustrates this condition.

A boy of 18 came for slight frequency. His urine was clear but contained a slight trace of albumin. Cystoscopy showed slight reddening around one ureter and on the strength of that he was sent into the house for a further study. When he came in a short time afterward I was unable to confirm the diagnosis. The bladder was entirely normal. The function of both kidneys was equal. The urine from both kidneys was clear and sparkling. There were no pus-cells from either side. There was the slightest possible trace of albumin from the supposedly affected kidney. Guinea-pig inoculation on this occasion showed no tuberculosis. I watched him very carefully during the following year. At one time a pig was reported positive from the sound side. He finally developed clear cut signs of renal tuberculosis and I did a nephrectomy. He went steadily down hill from the first with what was apparently a generalized tuberculosis. The kidney showed a tuberculous abscess in one pole without the slightest attempt at healing.

Corbus in a paper before this association in which he dealt with the question of immunizing patients before operation makes out a good case on the grounds of preventing a rapid dissemination of tuberculosis from the stirring up of the operation. Many other authorities have advocated a preliminary tuberculin treatment. If we reverse this evidence we find in it a very strong suggestion that there is no process going on in the body in this disease which has any marked tendency to cause healing or else the immunizing process would not be necessary. This seems to me to be the keystone to the whole question. If a person has a strong natural immunity to start with an initial infection will not gain a foothold. If a process does start in the kid

ney the slow course of the formation of anti bodies in comparison with the spread of the lesion allows the disease to get beyond the point where it can be entirely obliterated although it can often be walled off so efficiently that the symptoms cease and the condition becomes latent but capable of further mischief if for any reason it gets loose.

It would seem to me from a study of the cases reported in the literature from pathological study and from reasoning in connection with immunization that the healing of a tuberculous focus in the kidney is impossible.

OBSERVATION ON ONE HUNDRED AND THIRTY-THREE CASES OF GALL-BLADDER SURGERY WITH ESPECIAL REFERENCE TO THE POST-OPERATIVE TREATMENT

BY R I RHODES A B M D AGUSTA, CONN
 From the Jefferson Hospital, Rock, Vermont

THE cases reported in this paper were patients in the Jefferson Hospital prior to July 1 1915 and were operated upon by Drs Hugh H Trout and R L Rhodes. As this article is chiefly a post-operative study, lues malignancies, deaths, and of course non-operative cases are excluded. Though the number is small the value of hexamethylenetetramine seems so pronounced that it was thought appropriate to publish the results in order to stimulate a further study in other and larger clinics.

Of the 133 cases 32 were male and 101 female. Of the 32 males 18 suffered from cholecystitis 6 acute and 12 chronic and 14 had stones. Of the 101 women 22 suffered from cholecystitis 1 acute and 21 chronic while 79 had stones. Thus in men 43.75 per

cent showed gall stones whereas in women practically 79 per cent. Concerning the location of the stones 31 or 34.8 per cent were in the gall bladder alone 22 or 23.6 per cent in the gall bladder and cystic duct 7 or 7.5 per cent in the gall bladder and common duct 7 or 7.5 per cent in the cystic duct alone 3 or 3.2 per cent in the common duct alone 2 or 2 per cent in the cystic and common ducts and 1 or 1 per cent stones were found in the gall bladder, cystic and common ducts. It is odd that in none of these were stones found in the hepatic duct yet since July 1 three such cases have been encountered.

In women we had 56 cases under 40 years of age and 45 cases more than 40. In men 9 under and 23 more than 40 years of age. The table of ages according to decades follows:

	Male	Female	Total
d	1	0	1
h	1	2	3
h	8	20	28
h	5	34	39
tal	—	—	—
	0	56	56
	8	19	27
	10	—	31
h	3	4	7
h	2	1	3
tal	—	—	—
	33	45	78

re a definite history was obtained the
ive a history of typhoid fever in 59 per
f the cases, the women in only 24 per
pneumonia, men in 47 per cent and
i in only 18.5 per cent however the
made up for this by giving a history
pneumonia in 86.33 per cent. Jaundice
resent or had been noted in previous
s in only 48.5 per cent. The urine
thologic in 34 per cent which includes
es showing even a trace of albumin or
hyaline casts in other words anything
absolutely normal. There were heart
in only 15 per cent, including all
s other than absolutely normal the
st lesion being the Adams-Stokes syn
in a man 76 years old.

case is worthy of detailed report be
of the unusual clinical history

age 4 brought his son to the hospital
n acute appendix. The father obtained
a home in which there was case of typhoid
During his stay in town the father con-
us, giving a history suggesting a chronic
stitis over a period of about four years. On
l examination this was confirmed and such
osis given. He took his son home on th
lay. Five days later he returned t the
l with a very acute cholecystitis and t
on the gall-bladder was found distended
t the point of rupture. Cultures from the
s of the gall-bladder yielded a pure culture
ilus typhosus. He rapidly improved, the
ture was normal on the fourth day but
to rise again on the sixth day and con-
through a very typical typhoid fever, blood
and Widal both being positive. In the
week of his typhoid he developed a large
al abscess which when opened yielded
typhosus in pure culture following this,
valence was uninterrupted.

point of interest here is the very
assumption that, having a chronic low

grade cholecystitis, he fell a victim to poor
prophylactic precautions in the boarding
house and developed the disease, and as the
resistance of the gall bladder was already
lowered the acute infection manifested itself
there before it became systemic.

There were 4 cases in which the gall-bladder
gave symptoms during the course of typhoid
fever all of which came to operation with an
acute cholecystitis in less than three months
time. The operation consisted in the removal
of stones where present and the drainage of
the gall bladder by means of a large rubber
tube introduced into the gall bladder and
anchored with chromic catgut. The opening
in the gall bladder was closed with a purse-
string suture of chromic catgut, care being
taken to invert the edges. Two or three
cigarette drains were placed below and around
the gall bladder.

Post-operative treatment. The patients are
placed in bed in the prone position and
ordered to have nothing by mouth. Procto-
lysis by the Lawson method is given—water
dextrose or sodium bicarbonate, either or in
combination as indicated—and morphia gr $\frac{1}{8}$,
hypodermically every 3 hours, if necessary.
Water is usually not allowed by mouth within
24 hours if there has been any appreciable
nausea and is withheld longer if much nausea
or vomiting exists. Gastric lavage if in-
dicated.

In this series of cases the above outline
constituted the basis of the routine treat-
ment in 77 cases in which the average dura-
tion of drainage was 35 $\frac{1}{2}$ days. In 56 cases
in which the average duration of drainage was
39 $\frac{1}{2}$ days—a difference of over six and one
half days—the same treatment was used
and in addition hexamethylenetetramine in
doses of 50 to 80 grains daily. In cases in
which much pus was present at operation the
character of the discharge cleared up more
promptly in those getting hexamethylene-
tetramine. For example

A male, age sixty-two chronic cholecystitis with
subacute flare-up. In spite of free drainage he
continued to run temperature daily of 100 to 101
until the tenth day when he was given large doses
of hexamethylenetetramine. In two days it was
normal and remained so throughout the rest of his
stay in the hospital.

In none of these cases has there been any trouble referable to the gall bladder but among those who were not given hexamethylenetetramine several have had some trouble

One male age sixty had a cystic and common duct stone with a chronic cholecystitis which drained for 44 days. He returned to the hospital two months later with the history that his gall bladder had drained intermittently for five weeks. When not draining he would have attacks of pain nausea and vomiting such as before operation. During the last three weeks there had been no drainage and he had had five attacks. He was given hexamethylenetetramine in fifteen grain doses four times daily since which his symptoms have disappeared.

Another case a female age 24 had stones in the gall bladder and cystic duct which were drained for 48 days when she left the hospital apparently all right. Four and a half months later she returned to the hospital having had attacks of pain nausea and vomiting as before operation. She was given 10 grains of hexamethylenetetramine every four hours with prompt relief and has had no further trouble. Another case a female age 21 had stones in the gall bladder and an acute cholecystitis. On sixth day after operation her temperature ran up to 100. The wound drained thick mucopurulent material. Hexamethylenetetramine as begun and two days later the temperature began falling character of discharge improved until on the eleventh day the temperature was normal and bile drainage with very little pus in it. Further convalescence was uneventful.

In making this comparative study no attempt was made to select the cases but for the most part they were taken alternately with and without hexamethylenetetramine. The larger number without is due to the fact that those having been in the hospital before

the study was begun are included because the difference in drainage time is so marked it was thought best to get as large a number as possible for an average drainage time.

Even though the series is small it would seem beyond the realm of coincidence that those getting hexamethylenetetramine should have an average drainage of 60 days less and when it is noted that the character of drainage improves later and that the end results are more satisfactory inasmuch as not one who were given it have had any symptom referable to the gall bladder after leaving the hospital — as contrasted with at least four among those who did not — it would certainly seem that the use of hexamethylenetetramine would be a valuable adjunct to our post-operative treatment in lesions of the gall bladder and duct.

It is possible that the indication for cholecystectomy may be lessened especially in the sugary type in that there were several of the mulberry type gall bladder in the series who were given hexamethylenetetramine and who have obtained perfect relief.

NOTE — During the first few days following operation hexamethylenetetramine is given by proctocoly because at first the patient are not allowed fluid by mouth and later to avoid any possibility of upsetting the stomach. After the first week it is given by mouth. The idea has been to give the drug five days each week and omit for two days to prevent any untoward symptom. However should these develop earlier it is stopped for a day or two and then begun again.

PRELIMINARY HÆMOSTASIS IN GOITER OPERATIONS

By Dr. F. DE QUERVAIN, BASEL, SWITZERLAND
Professor of Clinical Surgery

GOITER operations are based on one of two principles: either the surgeon follows no special plan, excising the goiter as he would any other tumor and ligating the blood vessels as they bleed or he follows methodically a definite plan based on the anatomy of the thyroid gland. The first mentioned procedure predominated in the early days of goiter surgery; for the past 30 years, however, the methodical plan has been recognized as the only correct one.

Though most surgeons of the present day follow the second plan, their methods in operating still differ materially. Some show atavistic leanings toward the older method. It is true, they expose the goiter according to rule, free it from its surrounding tissues, and luxate it, clamping and ligating the vessels when blood flows. Others proceed more logically. The goiter once delivered the arteries are ligated successively as it is the area supplied by the arteries from which the principal hemorrhage may be expected. With this step it seemed the summit of logical operating had been attained. Yet it was not so.

Let us follow an operation on an exceedingly vascular goiter with strongly developed capsular veins. We find that the shelling out of the diseased gland from its enveloping thyroid fascia, the so-called external capsule and its dislocation can sometimes be an excessively sanguinary proceeding. If then, we apply ligatures to the most important arteries after luxating the goiter, we apply them too late for one of the most sanguinary stages of the operation. Therefore we see that to be really logical we should ligate the principal blood-vessels before shelling out and luxating the goiter. This line of reasoning led me five years ago to modify my operative technique which coincided with that of Kocher and to develop a method which would emphasize the principle of preliminary ligation more forcibly than had hitherto been the case.

The chief point in question was the ligation of the most important arteries before doing anything whatever to the goiter. In addition to the above mentioned motive of exposing and luxating the goiter with decreased hemorrhage a further consideration presented itself, viz. that the delivery of a profound, intrathoracic, richly vascularized goiter is much easier after the circulation has been interrupted than when blood is coursing through the blood vessels. Further my method protected the recurrent laryngeal nerves more efficiently than the technique heretofore used and the same time preserved the parathyroid glands.

I described my method first in December 1911 and then more fully in the spring of 1912.

After these few introductory remarks, I shall describe briefly how the different arteries can be ligated. We will begin with the *arteria thyroidea inferior*. As I explained in my previous paper, this artery is, as a rule, the chief source of blood supply to the goiter. Formerly, but quite wrongly, its ligation was supposed to be difficult. A glance at the accompanying schematic sketch (Fig. 1) will show us that this artery can be ligated at four different points.

a. Billroth tied the artery quite close to the goiter. Until recently Halsted ligated it at its entrance to or to be more exact, within the goiter ("ultraligation"). In our publication of 1912 we pointed out the disadvantages of his procedure and see with pleasure that Halsted himself has recognized our reasons, and that from his paper of 1913 he has given up ultraligation. We feel gratified that our views now coincide with those of an American surgeon who has probably contributed more than any other of his compatriots to the investigation and promotion of the anatomy of the goiter and the thyroid gland.

b. Kocher's method is much more expedient, as it secures greater protection for the

30 Pounds Live Steam Pressure

may be applied to tubes of D&G sterile plain or chromic catgut for sterilizing the exterior preliminary to operating, without impairing the physical integrity of the sutures!

Catgut of such stability is obtained only through the Claustro-Thermal method of suture sterilization using Toluol as a tubing fluid

IT IS IMPORTANT that physicians and surgeons should know that it is no longer necessary for those suffering from

Infantile Paralysis

(Acute Anterior Poliomyelitis)

to be weighted down with a heavy brace made of steel. *It Means Success and Reputation* to you to know where to secure for your patient the proper mechanical appliances which are light enough not to be a detriment and yet strong enough to assist those suffering from any deficiencies in body or limbs.

We believe we are the first, and so far the only Manufacturers of Orthopedic Apparatus in this country to introduce and use the metal known as *Dural min* which has sufficient tensile strength to insure efficiency in the appliance made of it and yet the weight is but one-third that of a similar appliance made of steel. We shall exhibit at the Clinical Congress to be held in this city in October a brace for *Infantile Paralysis* made of *Dural min* in our own factory by our skilled artisans — and we can show you, in our establishment, the raw material, as well as various finished apparatus.

Hessing's Spinal Corset

An excellent appliance to benefit those suffering from spinal irregularities — the aggravated cases where other braces would fail. One of these Corsets will be on exhibition.

By diligence and close attention to the desires of the profession, whose valuable suggestions we are ever ready to adopt, we have become the *Recognized Leaders* in the manufacture of

Orthopedic Apparatus

We have constructed appliances for many of the leading specialists in this line of work. Our constant study of orthopedic work through number of years has made us familiar with the requirements of the profession and all appliances are constructed in our own factory. Here we have every facility and can supervise the work from start to finish, thus assuring the physician and the surgeon neatly made and satisfactory appliances, which will redound to their credit through the appreciation and gratitude of their patients.

At your request, we will gladly send you cat-

alogues illustrating and describing every kind of Orthopedic Appliance of known merit and giving full directions for the taking of measurements which will enable us to make perfectly fitting appliances on receiving an order by mail from any section of the country.

We hope you will not fail to see our exhibit at the Clinical Congress and earnestly desire to have you visit our establishment. We are sure you

will find there much of interest to you, as you will see all that is latest in the way of instruments and appliances used in all kinds of surgical work.

CHARLES LENTZ & SONS

Manufacturers of Surgical Instruments and Orthopedic Appliances of Approved Design and Known Merit

Only five minutes walk from the Bellevue Stratford Hotel

DR CHARLES GEIGER'S Electro-Operative Surgical Bone Instruments and Accessories

Used and recommended by Dr. John B. Murphy, Dr. Fred E. Albee, and Drs. W. J. and C. H. Mayo

This set of instruments is especially made for transplantations, dowel-making and cranial work. It is not required to keep the cutters from burning the bone, in using the Geiger machine, because of the slow speed. A few of the many advantages not found in other motor bone instruments are: Sterilization of the motor, slow speed, great power, simplicity of the chuck, and the firmness with which it can be held.

Dr Charles Geiger's Orthopedic and Fracture Extension Device

makes orthopedic and fracture work easy for the surgeon, gives clear access, and removes all obstructions while applying plaster casts or dressings to hip or back, or any part of the limb. Perfect and continuous extension can be made on the smallest child as well as the largest man. The operating table is not in the way while applying dressings to the extremities, as found in all other extension apparatus.

This device is portable, and can be quickly attached to any operating table.

DR CHARLES GEIGER,

St. Joseph, Mo., U S A

SAFETY GAS-OXYGEN APPARATUS

*Shows what it delivers
Delivers what it shows*

A new and improved apparatus for the administration of Nitrous Oxide and Oxygen with or without an Ether Sequence in Major or Minor Surgery—Obstetrics, etc.

A perfectly controlled, even and continuous flow of any mixture desired.

Greater relaxation and ideal anaesthesia or analgesia.

Simple to Operate. Economical in Application. Perfect in Results.

Model "E" full assembled with gas tanks tested and all mounted on portable stand. Large tanks may be used as well as small.

A Truly Portable and Complete Outfit for Hospital or Private Use

Separate hand operated needle valve gas air mixers give simple and accurate control of their flow.

The New Positive Sight-Feed-Measurement enables you to see the flowing of the agents as you pass the animal further between the two. They enter the mixing chamber and the gas mixture is maintained as long as required. A glass at the opposite shows what flows at all times. (Never not absolutely accurate and maintained accuracy assured.)

Made in 3 models, D, "E" and F. Write for illustrated booklet containing full information.

Get showing Sight-Feed-Measurement. The level "A" in the Oxygen feed tube, and the level "B" in the Nitrous Oxide feed tube, tell us how much gas or less volume of the respective gas admitted to the mixing chamber by the needle valve. Accuracy of mixture and visible proof of accuracy. This is what

During the Seventh Annual Session of the Clinical Congress of Surgeons At Philadelphia

WE will, as has been our custom in former years have for your inspection a complete line of operating instruments apparatus etc for every branch of Surgery

You will find here instruments of special pattern made according to the exacting requirements of their authors

One of the items of special interest which will be shown is our

Universal, Noiseless Bone Surgery Equipment

with instantaneous stop hand piece. This engine can be used for bone transplants, cranial antrum sphenoid frontal-sinus and mastoid operations

HOGAN SILENT ROENTGEN TRANSFORMER

We Have Thrown the Motor Away!

In designing the Hogan Silent Roentgen Transformer we have eliminated the weakest point of other transformers the motor and rotary switch.

This type of transformer which equals if not exceeds that produced with equipment at a price for 1,200.00.

This is the Equipment of Economy in cost, tube cost, cost of wiring, and cost of maintenance.

And from this, does it do the work? Work well it, the salesman needed, will be told by mail.

Save the commission on that Roentgen equipment by writing in to the factory. Personal service from the factory on every machine built.

Ask for our catalogue and state whether you have an equipment to trade in.

Electrically Lighted Instruments

From the best material obtainable and by skilled workmen E. S. I. Co. instruments are made. Not alone are we the originators, but, as well, we are exclusive manufacturers of the most valuable diagnostic instruments now in use. Their position is firmly established among the profession and their usefulness is unquestioned by any who have tried any of the following:

Koch, Schickerson, Yarns, Gordon and MacGowan Urethrometers
Bruschi Cystoscopes, E. S. I. Co. V. and S. Models

These and many other instruments are described and illustrated in the Eighth Edition of Catalogue copy of which will be mailed upon request.

For your own protection be sure every instrument is marked "E. S. I. Co."

ELECTRO SURGICAL INSTRUMENT CO

ROCHESTER, N. Y.

This is a CO₂ Ice Crayon made in 2 minutes with a new Goosman instrument. Used in the treatment of over 40 different skin lesions. Price \$15.00. Order through dealer or direct from

New Device for Treatment of Oblique Fractures

(By F. W. Farham, M. D. and J. Desjardis Martin, M. D.)

A new simple and valuable method of treating oblique fractures. No more screws, no chance of loss of apposition as with Lane's plaster.

The force of the lever fits the band snugly around the bones. Slightly relaxing screw as instrument is turned over slit face band in position.

No Screws Required

No screwing up means time saved. This device consists of a band six inches by 3/16 inches, with slit one end and small hole in other. This band is passed easily around the bones, the free end is inserted through slit and made fast to pin on screw lever. Price with two bands \$7.50

Strain Eliminated

The strain involved in holding fragments in place with castorized plaster is eliminated. The band is set by a screw lever which is secured by a screw. The cut end is then pressed down and the band remains in position. The band is held in position by two bands, one on each side of the fracture. The band is held in position by two bands, one on each side of the fracture. The band is held in position by two bands, one on each side of the fracture. Extra bands, each \$0.25

"AMBUMATIC"

WASHABLE ABDOMINAL SUPPORTERS

Made buckled or laced. Adjustable as a band or to lower middle or upper part of abdomen as an uplift, carry the abdomen.

"AMBUMATIC" Supporters are slip proof of position from sudden strain lessening the action unprotected.

"AMBUMATIC" Supporters are light and comfortable to the wearer yet decidedly made and absolutely efficient. They enable the patient to resume work or business with perfect safety earlier than would otherwise be possible.

The "AMBUMATIC" Supporter is the best all-around success that anyone can buy following laparotomies.

The Morgan Ether Vapor Apparatus

AS USED IN MANY OF THE PRINCIPAL CLINICS IN BOSTON DURING 1918 CLINICAL CONGRESS OF SURGEONS

THE HARVARD UNIT USES THIS APPARATUS IN THE WAR ZONE

An Ether Vaporizer perfected by Ben Morgan, M. D. Chief of Anesthesiology, Boston Post Graduate School and the Chicago College of Medicine and Surgery. Anesthetist to Lakeside, Sheridan Park, St. Ann's, South Shore and Northwestern Dispensary Hospitals.

The distinguishing feature is the absence of pump or heating device to force the flow. The ether surface of efficient area to maintain desired concentration of vapor which is regulated at will by the operator.

Sent on approval to subscribers to *Surgery, Gynecology and Obstetrics*

RICHARD PIKE & CO

Gas Oxygen Anesthesia and Analgesia

The McKesson Apparatus

These machines are designed and constructed by a physician who knows the requirements of an apparatus for Hospital Office and Home use. Every element leading to perfection has been carefully worked out in the operating room and embodied in the apparatus mechanically.

To secure accuracy and constancy the patient's breathing automatically regulates the flow of gas and oxygen with each breath. All rebreathing is controlled by a graduated adjustable bag, which also measures the size of the respiration and operates automatically. An emergency valve is provided for artificial respiration with pure oxygen.

The Junior is designed especially for Analgesia in Obstetrics and painful deliveries also for short anesthetics for minor surgery. In its carrying case it weighs only 15 lbs. trifling large than microscope case.

The Junior model is light, simple and automatic for analgesia, requiring no one with experience to adjust or regulate it. The patient herself can apply and remove the mask as directed by the obstetrician, and secure good results.

Fig. Schematic outline of the fasciae and spaces in the region with the thyroid gland obtained by means of injections into the anterior and posterior jugular spaces. The fasciae are depicted by curved lines, more or less thick, depending on their importance.

A: thyroid space (patium thyroideum); B: sternohyoid space (patium sternohyoideum); C: sternomastoid space (patium sternomastoideum); D: space containing blood vessels. The spaces are here schematically outlined as are actually enlarged by the mass injected.

1: Entrance to the anterior thyroid artery; 2: the purpose of this ligature (de Ouverain method); 3: Entrance to the posterior thyroid artery; 4: Cystic proper of the thyroid gland; 5: the so-called internal jugular; 6: Internal fascia of the small muscles; 7: the so-called internal jugular; 8: External fascia of the small muscles; 9: Sternohyoid muscle; 10: Entrance to the inferior thyroid artery; 11: inferior goiter operation; 12: Bulbous method—Kocher applies the ligature more laterally; 13: Sternohyoid muscle; 14: Halsted ultraligature; 15: Sternocleidomastoid muscle; 16: Sternohyoid muscle; 17: Common carotid artery; 18: Parathyroid gland; 19: Internal jugular vein; 20: Entrance to the trunk of the inferior thyroid artery; 21: Recurrent nerve; 22: Durovnik, Alama, and Roger; 23: Sympathetic nerve; 24: Inferior thyroid artery.

recurrent nerves and the parathyroid. The ligature is applied after the goiter has been lifted from its bed in the space between the thyroid gland and the thyroid fascia but as laterally as possible. One slight disadvantage

of this method however is that when seeking the artery we are not separated by a layer of fascia from the recurrents and the epithelial bodies; therefore the care of these two structures demand great attention. The result

Fig. Special instruments for goiter operations. 1 and 2 retractors of different sizes. 3 long blunt dissector, 4, narrow elevator used for raising and detaching the inferior artery from its surroundings, 5 fine sharp, no (Cooper's) needle.

hitherto obtained and still obtained by Kocher and many other surgeons by means of this method prove that with sufficient practice the above mentioned structures may be protected with a good degree of certainty. Still one disadvantage remains viz. in order to reach the artery the operator must penetrate the space containing the most veins consequently there is risk of extensive venous hemorrhage before reaching the artery especially in the case of richly vascularized goiters, and more particularly in the case of Graves disease.

c. Surely then it must be more advantageous to ligate the artery somewhat farther away from the goiter in the space containing the small thyroid muscles, outside the thyroid fascia (the so-called external capsule of the goiter). This is the method we have employed since 1911. Later on we shall describe it more fully.

d. Finally we can ligate the ascending branch of the artery as Dietrich first and

later Langenbeck seem to have done, on the outward side of the carotid artery. To this end Langenbeck incised transversely the sternomastoid muscle whereas Drobniak, taking into account the regional anatomy proposed penetrating laterally from the outside border of the above named muscle a proposal adopted again later (25 years ago) by Billroth, Rydygier and Woelfler also by Reverdin and recently by Alamartine and Rogers. It is clear that in proceeding thus the surgeon intervenes at quite an unnecessary distance from the field of the operation. Moreover as far back as 1891 Woelfler drew attention to the fact that this method is conducive to lesions of the sympathetic nerve. Old as it is, it does not seem to have found its way into the practice of goiter surgery and Alamartine's most recent recommendations of it are based only on anatomical considerations. Rogers only has employed it in 37 of his cases.

The foregoing demonstrates that we prefer ligating in the space between the outer plane of the thyroid fascia and the inner side of the carotid artery.

Before entering into further details we must say a few words about the spaces and fasciae round about the thyroid gland. By means of gelatine injections we have in various ways investigated the thyroid region in cadavers. Mr. E. C. Jones translated in this journal a summary of these investigations from our article mentioned above. It was however unduly ascribed to Poulsen whom Jones mentioned on account of his investigations of the other fasciae of the neck but who has never examined the spaces round about the thyroid gland.

Our method of procedure was as follows. We injected differently colored gelatine into the various interstices round about the thyroid gland of the cadaver. A transverse cut through the neck after the injected mass had hardened showed us the extension of the different spaces now filled out with gelatine. We devoted another series of experiments to the special study of the fasciae, proceeding as follows. We injected completely transparent gelatine under high pressure into all the

At the Carotid Artery.

Fig. 3. Skin and platysma incised. Muscle at rhinocleidoma tied up, treated outward. The internal fascia of the small muscles, vertically lined, for the sternohyoid muscle.

spaces. We then excised a transverse section 2.5 centimeters thick from the neck, fixed it in Kaiserling's solution and embedded it in transparent gelatine. Thus we obtained excellent preparations which had so to say been artificially rendered oedematous to such a high degree that the course of the fasciae could be traced into their very finest layers.

The arteries of these preparations were filled at the same time with red and the veins with the blue gelatine. The anatomical conditions found were the following (Fig. 1).

The thyroid gland is enveloped in a thick layer of its own fibrous tissue called the capsule propria (according to Kocher the epithyroidium). This fibrous envelope cannot be detached from the thyroid gland as for instance the fibrous capsule can be detached from the kidney or to be more exact it forms an integral part of the gland. The

thyroid gland is surrounded by a space containing fine layers of connective tissue and veins. This space into which only a liquid mass can be injected is called the *spatium thyreoideum*. In front it is bounded by a layer of fascia viz the inner fascia of the sternohyoid muscle which more laterally forms the median boundary of the blood vessel sheath. We adopt for it the same name as Corning and other anatomists the *thyroid fascia*. It corresponds with what is generally called the *external capsule*. More posteriorly this fascia separates into single lamellae which take their way to the trachea, the oesophagus and the spinal column. Around the thyroid fascia we find another space containing muscles viz the sternothyroideus, the sternohyoideus and a portion of the omohyoideus. We call it the *spatium sternohyoideum*. Its outer wall consists of a strong fascia viz

Fig. 4 Small retractor in position. Sternohyoid muscle exposed. The forefinger will now be deep! incision in median direction to seek and expose the inferior thyroid artery.

the outer fascial covering of the sternohyoid muscle. As such it overlies the thyroid region stretching from there to the rear. On the outer side of this space we have finally the space containing the sternomastoid muscle the *spatium sternomastoideum*. The blood vessel sheath lies to the rear of the spatium thyroideum and the spatium sternohyoideum. The chief component of its median wall is the fascia thyroidea its anterior outer wall being formed by the fascia thyrohyoidea. Behind the blood vessel sheath and anteriorly from the profound neck fascia the inferior thyroid artery takes its upward course penetrating the posterior portion of the thyroid fascia on the median side of the carotid artery. The parathyroids and the recurrents — the latter within the field of operation — are both situated in the spatium thyroideum. For that reason and because

it contains numerous capsular veins we avoid the spatium thyroideum as an entry to the arteria thyroidea inferior. Therefore we have at our disposal only the spatium sternomastoideum. The last named space starting from the median border of the sternomastoid muscle is the one which has since the time of Velpeau, Farabocuf and Kocher been noted in surgical textbooks as the best entry for the application of an isolated ligature to the inferior thyroid artery. The operator frees the median border of the sternomastoid muscle and then penetrates between it and the fascia of the sternohyoideus. Certainly the artery sought for can be reached in this way, but the jugular vein is always reached first and is liable to injury if great precaution is not exercised. The following course which we proposed for the first time in 1911 is therefore very much to be preferred.

Fig. 5. A larger sized retractor has now been inserted. The inferior thyroid artery has been bluntly disengaged from its surroundings and will be ligated.

We employ Kocher's collar incision dividing at one sweep the skin, subcutaneous fat and platysma myoides. After ligating the superficial veins we free the median border of the sternocleidomastoideus and draw it so far outward with a blunt retractor that the surface of the anterior fascia of the small muscles becomes visible. We then make a vertical slit of about 2.5 to 3 centimeters long in the latter mentioned fascia (Fig. 3), pare it back bluntly and catch it up with the retractor (Fig. 4). We now work bluntly with a finger insinuating it deeply in a median direction along the median side of the common carotid. This artery we release from its median surroundings and come into touch almost immediately with the arteria thyroidea inferior which passes at a right angle to and underneath the carotid artery in a median direction (Fig. 5). If necessary we now replace the retractors by others reaching some

what deeper so as to bring the artery into view and with the aid of two long blunt dissectors 17 centimeters in length (Fig. 2) separate and raise it from the deep neck fascia with a narrow elevator we have had made especially for the purpose (Fig. 1). The ligature thread is now slipped round the artery with an especially lightly constructed Cooper's needle. In simple cases the whole proceeding from the skin-cut to the tying of the ligature does not take more than a few minutes.¹

As a rule no vein whatever except one or two surface veins interferes with the application of the ligature. In other cases the vena thyroidea media crosses the arteria thyroidea inferior. However the operator is rarely obliged to ligate the vein in order to gain access to the artery.

¹ This method is briefly translated from my paper and published in *J. Soc. & Obst. Gyn.* by E. O. Jones but is original.

Fig. 6. Spatium sternothyroideum is dissected and a view is now obtained somewhat more medially, through the small muscles and the thyroid fascia immediately in front of the thyroid gland (in the spatium thyroideum). The goiter is retracted downward and before ligating it, in order to ligate the superior thyroid artery or its inferior branch.

The ligature applied, the question arises as to whether the goiter itself requires surgical treatment. If so we leave our space work our way in between the small muscles (Fig. 7) free the goiter whose capsular veins now hardly bleed at all luxate the goiter and undertake whatever the existing circumstances demand excision, resection or enucleation as shown in the accompanying illustration (Figs. 7 to 9).

The inferior thyroid artery being as we know somewhat less regularly existent than the superior and its course also less regular we ask ourselves how often the ligature can be applied in the above-described manner. During the first period in which we operated on these lines, it was possible in 89 out of a hundred cases. In a later series we met with no obstacle in 95 out of a hundred cases.

In only 5 cases was the ligature impossible owing to the non-existence of the inferior thyroid artery or to its too profound situation.

The only real difficulties in the way of applying the ligature in the above-described manner occur when for instance the artery is situated too far thoraxward, or is too far overlapped by the goiter. In most cases the two obstacles may be overcome by using sufficiently long suitably constructed retractors. Sometimes the operator is surprised during the subsequent goiter operation by an unexpectedly strong hæmorrhage after having as he supposes accurately ligated the artery. The reason of this is generally that the ligature has only been applied to the superior branch of an inferior thyroid artery which divides abnormally near to its origin. In reality this occurs

Fig. 1. Diagram of the goiter operation.

T. 100

much less frequently than certain anatomical investigations would lead us to expect.

One condition demanding attention is that it may lead to most unpleasant results. In this instance it may happen that when the surgeon is about to slip the Cooper needle around an inadequately separated artery or has inadvertently tied the ligature too tightly a brittle vessel tear or is cut through and it is not always easy to locate the vessel again. This of course is more likely to occur in the case of older persons or persons with Graves disease. These unfortunate circumstances may all be avoided by carefully isolating the artery with two blunt dissectors and the narrow elevator and by not drawing the ligature thread too tightly. In the case of brittle arteries it is advisable to employ a strong catgut.

The neighboring organ and structure to be considered are the trachea and

the posterior lobe and the subcutaneous tissue.

The handling of the trachea is very easy at the level of the ligature. It is separated from the artery by the previously described thyroid dissection and is invisible during the whole operation which is one of the chief advantages of my method.

On the goiter we operated upon from the beginning of July 1911 until the end of August 1911 we had the opportunity of examining at a later date 30 cases and especially of ascertaining the exact condition of the vocal chord. Among the 19 cases operated on according to my method comprising 6 ligatures of the inferior artery.

In only one case of permanent paralysis of the recurrent nerve had occurred and that not in consequence of the ligature but of the handling at the exact junction between which and the trachea an adhesion had to be

Fig. 8. Gouter removed by means of resection, enucleation, or combination of both. The largest veins and the anterior branch of the superior thyroid artery are ligated. The smaller ones have been drawn into the harmonic suture. A lobe of almost normal size has been formed out of the remaining gland tissue.

severed. Two further cases of permanent paralysis of the vocal chords occurred after operations on the old lines (intraligamentary ligation of the artery). In 8 cases we found paresis such as any method may occasion through stretching of the nerve during the process of luxating the gouter. All these 8 cases of paresis were on their way to recovery. The cause of these paralytic conditions was not always to be determined with any amount of certainty. Particulars of the cases will be found in my recent paper and in that of my assistant, Dr. Hoessly, in the *Deutsche Zeitschrift fuer Chirurgie* December 1915. The chief point is that among 250 gouter operations only 3 cases of permanent injury to the recurrent nerve occurred, and that of these 3 only 1 occurred among the 197 cases operated on with the new method.

Secondly the parathyroids must be protected. The thorough investigations, notably of Erdheim, Halsted, Geis, Evans, Bérard, Alamartine and Iversen, with regard to the blood supply of these organs, prove that each of them is supplied by a fine branch of the *arteria thyroidea inferior* or by the branch artery connecting the inferior with the *arteria*

thyroidea superior. A little simple reasoning will make it clear that this fine blood supply can most effectually be protected by ligating the large arterial trunks as far away from it as possible. This course alone insures the safety of the fine *arteria parathyroidea* during the operation and provides as large a field as possible for the collateral circulation. Therefore the farther away from the thyroid gland a ligature is applied to the inferior thyroid artery the less the danger of injury to the parathyroids. For the past five years I have advocated this principle and am glad to see that it is becoming more and more recognized. Up to the present I have in more than 200 cases tied both the inferior thyroid arteries at one sitting and have never seen a trace of tetany. Neither have I found this condition in the numerous cases, in which I have simultaneously ligated three arteries, or when ligating the two inferiors, one superior and the front branch of the other superior thyroid artery. We can therefore say that tetany is not the result of the ligature itself but the result of a ligature improperly applied.

The third organ demanding protection is

the sympathetic nerve. Hitherto it has received but little attention and many surgeons have severed it with therapeutic intent in cases of Graves disease without considering the far from pleasant consequences of a sympathetic paralysis especially the consequences of a sympathetic ptosis and miosis. Just the last named symptoms demonstrate the desirability of shielding the sympathicus especially when Graves disease is not the cause of the goiter. In such cases nothing could justify a lesion to the nerve. Our investigations show that the sympathetic nerve is somewhat more endangered by our method of ligation than by the older method. Certainly more exact investigations on injuries to the sympathetic nerve in the course of other methods of goiter operation are lacking. It is principally in danger of being crushed by the retractor used to draw the carotid outward. Among the 250 cases we subsequently examined there was only one of decided sympathetic paralysis and three with slight pareses. In several cases the nerve was defective before the operation. These figures show that the danger is not great. At my request Professor Metzner and Dr. Woelfflin have investigated the sensibility of the sympathetic nerve with regard to traumatic lesions and have found that in the case of rabbits a traction of 10 grams a minute is the maximum that can be endured without a reaction on the part of the nerve. An increase in weight of 15 to 20 grams produced regularly vascular and ocular pupillary symptoms the latter of which completely disappeared in only a few cases. Still in order to reduce even this slight danger I have constructed the retractor I employ for drawing outward the carotid artery in such a manner that it does not rest on the vertebral column with a long edge but with only two supporting knobs. Thus the risk of nerve lesion is but slight (Fig. 2 r).

We will now proceed to the ligation of the arteria thyroidea superior. On this point there exists less difference of opinion. We therefore will also treat it briefly. If only one of the superiors is to be ligated it can be done from a short transverse cut made precisely in the line of the skin folds at a level with the thyroid cartilage. If the two supe-

Fig. 9. Pla. of the goiter operation. 1 (also c) R. section of both lobes B on sided enucleation R recurrent nerve E epithelial bodies.

riors are to be occluded a corresponding cut is made on the other side and the operation carried out in the same manner whether it be a question of pure arterial or pole ligation. If however in addition to the superiors the inferiors and the goiter itself are to be included in the operation all can be done as Tavel was the first to prove ligation of superior and inferior arteries lobectomy etc. from the usual collar incision. The entry this incision provides is ample for the ligation of the superiors if only the upper skin flap is drawn sufficiently high upward and the small muscles retracted outward and upward (Fig. 6). As a rule it is quite unnecessary to luxate the goiter before applying the ligatures. On the contrary we generally ligate the superior thyroid arteries before dislocating the goiter whether we restrict ourselves to ligatures or undertake further intervention (Fig. 6).

The question now arises as to how many arteries should and may be ligated. That depends entirely upon the object in view. If a diffuse goiter or more particularly a goiter caused by Graves disease is to be treated with ligation only the surgeon should not be too timid. Ligatures applied to only two arteries whichever they may be do not seem to me sufficient to attain a lasting effect, even if the primary result appears satisfactory.

For that reason I always ligate preferably at one operation more rarely at two three to three and one half arteries i.e. all the thyroid arteries with the exception of one superior or the posterior branch of one. This operation if properly carried out, will by no means interfere with the function of the parathyroids. According to the results of different surgeons their function does not appear to have suffered even after the occlusion of all four thyroid arteries (Rogers). Still, for my part, I have until now preferred to confine my ligatures to three and one half arteries. We know for certain that ligation is only efficacious in cases of diffuse, and especially of extremely vascular goiters, and is even then not to be completely depended on. My later examinations of patients operated on have convinced me that only small diffuse goiters recede sufficiently. Medium sized goiters certainly do shrink a good deal they cannot, however be reduced by ligation alone to anything like the ordinary volume of a normal thyroid gland. The collateral circulation between the thyroid gland and its neighboring organs is, in spite of the absence of a more extensive arterial communication so plentiful that the gland remains viable even after the occlusion of all four arteries, if only it is not too radically separated from the surrounding structures. Experiments on animals have also proved this fact.

In conclusion we have to consider the value of ligation in the various goiter operations. We have employed it extensively in our surgical practice and are more and more convinced as to its advantages. It is understood that many operations especially enucleation can also be easily performed without preliminary ligation. It has, in fact, been laid down as an axiom that enucleation should be undertaken without preliminary ligation so as to preserve as much healthy gland tissue as possible. This conception originated in an undervaluation of the advantages of preliminary hæmorrhage, and especially in an undervaluation of the importance of the collateral circulation as a source of nourishment for the thyroid gland.

Now we know that the supply of blood to the remaining tissue of a thyroid lobe operated on is not endangered by the ligation of an inferior if only the posterior branch of a superior is left intact, and if we do not unnecessarily sever the isthmus with its border arteries. Our subsequent examinations of cases operated on have indeed proved that the preservation of the isthmus (Fig. 9) provided this organ is not decidedly diseased in no way impairs the result of the operation. Therefore in the 250 cases reported in our statistics we did not once completely sever the isthmus. In only 29 cases, in which it was in an advanced goitrous condition, did we partially remove it. By the preliminary ligation of an inferior — this is generally the more important artery — enucleation becomes a much less sanguinary a clearer and a neater operation. At the same time we can avoid hasty clamping and too extensive pouch sutures when surprised by unexpected deep hæmorrhage both of which steps mean grave risk for the recurrent nerve. If both lobes contain larger nodules the preliminary ligation of both the inferior arteries permit us to shell out neatly the largest nodules from both lobes, instead of restricting the operation to the more simple, but less logical excision of one whole lobe which always places the surgeon in a quandary if later he is called on to intervene further in consequence of the disturbance caused by the goitrous condition of the other lobe.

The foregoing remarks apply still more particularly to the operation of diffuse colloid goiters. The ideal method is then reduction of both lobes by means of resection which can be achieved without unnecessary loss of blood only by preliminarily ligating arteries on both sides. Then again it is better to ligate the inferiors, so as not to risk injuring the recurrent laryngeal nerve. If the inferiors and the anterior branches of the superiors are ligated on both sides the operation can in most cases, be performed calmly and without hæmorrhage and an adequate supply of blood is insured for the remaining thyroid tissue and the parathyroid glandules.

THE RELATION OF ARTERIOSCLEROSIS AND OTHER ANATOMICAL CHANGES OF OLD AGE TO THE DEVELOPMENT OF EPITHELIAL MALIGNANCY¹

A STUDY OF 206 CASES OF CARCINOMATA
BY FRANK WARNER M.D. F.A.C.S. COLUMBUS, OHIO

IN treating of the so-called precancerous conditions, various authors have presented us with an amazing amount of literature during the past decade. As a result of these studies one practical result has followed. The surgeon has been enabled to see and treat his cancer patients much earlier than before. Less mutilation has followed these earlier operations and many lives have been saved that before would have been lost.

Bloodgood² and others have presented the clinical picture of those breasts whose epithelial cells are about to take on or recently have taken on an abnormal growth. He has given the surgeon a very tangible and useful description by which he may recognize those conditions of the lip which if not promptly and radically treated will destroy the patient's life.

From a histological study of these precancerous conditions a number of research workers, including Greenough and Hartwell,³ Speese,⁴ Klotz,⁵ MacCarty,⁶ Means and Forman,⁷ have confirmed this work of Bloodgood and are agreed that the essential anatomical changes in these conditions are—

1. Increased activity on the part of the epithelium.
2. Increase in the connective tissue especially in the amount of intercellular substances elaborated.
3. And lastly an obliteration of the lumen of the blood vessels.

It is to be noted that a majority of the workers have been intent upon a search for landmarks by which the surgical pathologist might recognize the malignant change before

actual penetration and infiltration had taken place. Some of them however have attempted to submit theories to explain how these anatomic changes might so disturb nutrition as to become factors in the production of carcinoma.

In a study of the only cancers which have been produced experimentally Wyss⁸ and Wilbach⁹ are agreed that such cancers are the result of altered nutrition and this in turn is dependent upon a narrowing or obliteration of the lumen of the subepithelial blood vessels supplying a certain group of cells. This condition follows X-ray burns.

Thalheide¹⁰ has placed great stress upon certain old age conditions as causative factors in the production of carcinoma.

Chief among these old age conditions having an etiological role he places endarteritis. He says: "When organs which have been invaded by cancer are examined one usually finds in the connective tissue about the growth very few cells, blood vessels which are stenosed and with thickened walls and signs of endarteritis obliterans. An exception to this is noted however in that the tissues immediately surrounding the cancer show a more or less marked reactive hyperemia with cell infiltration usually of slight degree."

I drew the conclusion from these and many similar observations that the local disposition of aging tissue to cancer results from a diminution of the cellular elements and a contraction of the blood vessels in the connective tissue.

In discussing these anatomic changes which are assigned by some of these workers an etiological role in the production of carcinoma Loeb¹¹ said: "Some accuse the ob-

literation of the blood-vessels this condition it was argued forced the epithelial cells to obtain their food supply from the connective tissue cells which latter process was said to act in a similar manner as the penetration of a spermatozoon into an ovum a somewhat fantastic comparison with barely any foundation of fact.

Others assumed, he continues, that chronic connective-tissue changes liberated the latent energy of the epidermis. It is, however difficult to see why very dense connective tissue should as such be favorable to epithelial growth. In all probability he concludes, it would prove very resistant to the expansion of the epithelium. He dismisses the etiological importance of this fibrosis with the observation that in many cases of cancer of the skin no such changes are found.

With this variation of opinion in mind it would seem desirable to take as large a number of carcinomata as time would permit and study them to ascertain whether these anatomic changes were at all a constant accompaniment of cancer. This is such a study based upon the examination of 206 cases of carcinoma. Their distribution can be seen in the appended table (see Table I).

Since most of the workers mentioned above have concerned themselves with carcinoma of the skin the epidermoid type will be considered first. The histological study of the condition of the tissues involved in the epidermoid carcinomata revealed in many instances a distinct stenosis of the lumen of the arteries supplying the part, and frequently a like condition in the smaller vessels. In this study consideration has been given only to those cases in which the arterial changes have produced a stenosis of such pronounced type as would indicate that it probably antedated the development of the cancer and of such a degree as to be capable of interfering materially with the nutrition of the area involved.

The percentage of cases in which these anatomic changes were present varies with different sites studied. Whether these figures would hold if a larger series were examined is somewhat doubtful.

Seventy six epidermoid carcinomata occurring in various parts of the body were examined. Of these 76 cases, 44 or 57 per cent, showed a distinct obliterative change in the lumen of the arteries. The connective tissue surrounding 47 cancers, 61.57 per cent of this series was characterized by the presence of few nuclei and a rather large amount of intercellular substance. There was a marked lymphocytic infiltration present in 57 or 73.68 per cent, of the specimens.

While this series is not a large one yet it does show one thing namely that the anatomic changes (obliteration of blood vessels and fibrosis) are not constant in epidermoid carcinomata. It would therefore not appear safe to place too great stress upon their etiologic role in the production of this type of carcinoma.

Since arterial changes are known to occur so frequently in the uterus, it seemed best to examine a series of non-cancerous cervixes from patients of the cancerous age as a control. Twenty specimens from women over 35 which had been removed because of erosions or scars were studied.

Of the 20 cases examined, 8 or 40 per cent, presented endarteritis leaving 12 or 60 per cent, normal vessels. Nine or 45 per cent had an acellular stroma, 3 of these with connective tissue increase and 6 with fibrosis. Four or 20 per cent were infiltrated with lymphocytes.

If this control series is compared with the cancers of the cervix it will be found that 79 per cent had sclerosed vessels in the cervixes and 40 per cent in the non-cancerous cervixes, an acellular stroma in 50 per cent of cancers, and 45 in the non-cancerous cases, a lymphocytic infiltration of 79 per cent in the cancers and 20 per cent in the benign cervixes.

HAIR MATRIX CARCINOMATA

Thirteen hair matrix carcinomata were studied. Eleven of these cases were from the face on or above the upper lip which is quite characteristic of this form of cancer. Occasionally they do arise in other parts of the body as in these cases one was from the region over the scapula, and another from leg.

This type of cancer arises at the hair follicles from the epithelial cells of the hair follicle. In their growth, tumor cells of this type tend to differentiate as do the cells of the hair matrix and form the characteristic nodule.

They also tend to form tubules as would be expected from their origin. The cells themselves are frequently spindle celled or tuboidal and often appear in a rather compact arrangement.

Hair matrix carcinomata seldom invade the deeper structures and so are perhaps less malignant than any other type of carcinoma. It removed by a rather wide incision they are not likely to recur. This is shown by two of my own cases in this series one of which was removed some five years ago and the other two years without sign of recurrence in either instance.

In the examination of this group of 13 hair matrix carcinomata 10 of the cases showed a dense connective tissue beneath the epithelium and surrounding the hair follicles which was poor in nuclei and rich in intercellular substances. Arterial tenosis was noted in only 3 or 38.5 per cent instances.

in the breast tissue.

THE BREAST

Five cases of breast cancer were examined. In 3 the cancer was of the ductal type and in 2 the cancer was of the lobular type. In all cases the cancer was of the ductal type and in 2 the cancer was of the lobular type.

In the breast tissue the cancer seems to possess the power of stimulating the growth of connective tissue even to a marked extent in the benign tumors the so-called fibroadenoma. In the malignant cases it was not surprising to find connective tissue increase in all of these cancers except the most cellular and rapidly growing ones. Out of the entire group of 5 cancers of the breast there were but 4 those of a medullary type that did not show fibrotic changes.

In a control series of 10 specimens of abnormal involution of the breast only 3 cases, 30 per cent, presented arterial sclerosis change and 16 or 60 per cent with infiltration of lymphocytes.

All of the control series exhibited fibrosis. This is a part of the histologic picture of an involuting breast.

From the fact that cancer of the breast is so frequently associated with abnormally involuting breasts many clinicians and pathologists have come to regard this state of the gland as a precancerous condition requiring removal of the organ.

The vascular changes in the cancers were 58 per cent compared with 25 per cent of sclerosed arteries in the non-cancerous specimens, and there was infiltration of lymphocytes in only 16.66 per cent, cases in the controls.

In studying the specimens of abnormal involution of the breast with reference to the anatomic changes of endarteritis, fibrosis and epithelial proliferation, it was found that the acini were not only increased in number but frequently the fibrotic changes were so marked that their secondary contraction had occluded the ducts, resulting in a formation of cysts, which has given rise to the more common term of chronic cystic mastitis.

Often the acini and ducts were filled with proliferating cells but by carefully examining the surrounding connective tissue, it was plain that there had been no infiltration with epithelium. Not alone that, but the acini although greatly increased in number were more uniform in size than when the breast had taken on a malignant type of growth.

ADENOCARCINOMA OF THE UTERUS

A series of 8 cases of adenocarcinoma of the body of the uterus were examined. Five cases, 62.5 per cent, presented arterial obstructive changes; 2.5 per cent, were acellular; 3.375 per cent, had been infiltrated with lymphocytes.

A study of nine cases of non-malignant uteri of the cancerous age was made. The uteri had been removed for various reasons other than cancer. Three 33.3 per cent, presented sclerotic vessels; one 11.1 per cent, gave an acellular connective tissue, but there was no lymphocytic infiltration in any of the 9 cases.

As will be noticed from this series the percentage of vessels sclerosed was less than in the preceding cancerous series of uteri, although there they were involved in a little more than half of the cases. The same obser-

vation is true with reference to the condition of the connective tissue in the region of the carcinoma.

THE PROSTATE GLAND

Twelve cases of cancer of the prostate were examined. Four 33.33 per cent, of these specimens had been attacked by arteriosclerosis and 3.25 per cent showed the connective tissue to have been increased in amount and exhibiting few nuclei. Lymphocytic infiltration was present in 9 cases 75 per cent.

McGrath¹ has called attention to the analogy which exists between the microscopical pictures of the epithelial changes in the cancerous process of the breast and prostate. While this study does not assign much etiologic role to vascular stenosis, it leads to an agreement with McGrath as to the nature of the process in both of the organs mentioned. Whatever stimulus initiates the process, it passes through a gradation of epithelial hyperplasia which is often easily followed in a single case. Frequently the various steps may be seen in the same slide. Acini are seen in which both the inner and outer layers of cells are distinct (the primary hyperplasia of MacCarty). Other areas of acini exhibit a piling up with epithelial cells by a proliferation (secondary hyperplasia) and finally areas are found in which the epithelium has broken through and is infiltrating the surrounding tissue (tertiary hyperplasia).

CONTROL SERIES OF HYPERTROPHIED PROSTATES

Ten cases of hypertrophied prostates were examined. The average age of these patients was 60.7 years. Seven of the prostates were cystic in type. But one of the cases showed obstructive sclerotic changes in the vessels. Hyaline degeneration was manifest in a number of the arteries of the specimens. Two of the prostates, 20 per cent showed acellular connective tissue increased in amount. Six, 60 per cent, presented lymphocytic infiltration.

By a comparison of the hypertrophied with the carcinomatous prostates studied, one finds 10 per cent of the former with sclerosed

vessels while the latter shows 33 per cent with arterial obstructive changes

In the hypertrophies 20 per cent showed connective tissue increase of an acellular type while 25 per cent of the cancers of the same organ showed a like fibrotic change. Lymphocytic infiltration was present in 60 per cent of the hypertrophies and 75 per cent of the cancerous prostates

If obstructive endarteritis is one of the occasionally contributing factors in the development of cancer it was absent in 8 cases 66.66 per cent which had normal vessels out of the 12 specimens examined. The same holds true of the cancerous prostates in which fibrotic changes were present for 75 per cent of them presented a normal connective tissue

CARCINOMA OF THE OVARY

A series of 10 carcinomata of the ovary were examined. Three or 30 per cent showed vascular changes of an obstructive character. But 1 or 10 per cent presented acellular fibrotic changes in the connective tissue. Lymphocytic infiltration was present in 3 of the cases 30 per cent.

A peculiar feature of this series was the large percentage 70 per cent, of cases with normal blood vessels. Another notable fact was the absence of fibrotic changes in the ovary except in a single case of the series. These facts stand out with increased force when we come to reflect that it is a very common thing to find ovaries removed for other causes in the so-called cancerous age permeated with sclerosed vessels also to find frequently fibrotic changes in these organs. But here are 7 out of 10 cases with normal vessels in the presence of cancer and only 1 with fibrotic change while there are numberless cases of ovaries with sclerosed vessels and fibrotic changes without carcinoma. The type of the tumor might influence the findings somewhat, as 7 of these were papillary cystadenomata

CARCINOMA OF THE STOMACH

Seventeen cases of carcinoma of the stomach were examined. Six or 35.52 per cent presented sclerotic arteries a very low per

centage compared with what obtained in carcinoma of the cervix uteri. Four 23.52 per cent showed lymphocytic infiltration which is small compared with some other localities. Four gave an acellular connective tissue increased in amount 23.52 per cent.

A very interesting question in regard to these cancers is whether they develop from preceding ulcers of the stomach or the ulcer develops from the carcinoma. By analogy we should expect to see a carcinoma develop from the fibrous tissue about an ulcer just as a cancer frequently develops from the fibrous tissue of an involuting breast and from the dense tissue following X-ray burns. We are all familiar with Mayo's views that cancer frequently develops from an ulcer. Upon the other hand Stromeyer thinks the majority of these ulcers associated with carcinoma have been entirely secondary to the cancer and have been superimposed upon it (Figs 9 and 10).

The small series of twelve cases of adenocarcinoma of the intestinal tract other than the stomach were examined. Eight 67 per cent showed arterial obstructive changes 5 4 57 per cent a fibrotic change and 3 25 57 per cent lymphocytic infiltration. One of the specimens was from the œsophagus two from the ileum and three from the colon. Of the 6 cases of the rectum included in the above series there were 50 per cent with arterial changes one fibrotic and 2 with lymphocytic infiltration. In 5 of the cases of this series the cancer-cells had shown their ability to stimulate the connective tissue overgrowth to an extent that had resulted in an almost complete obstruction of the alimentary tract when this excessive tissue underwent contraction for whenever newly formed connective tissue in a circular tube undergoes contraction as it will stricture results. But this is a feature that is outside the discussion of this study of the etiology of cancer.

PRIMARY CARCINOMA OF THE LIVER

Four cases of primary carcinoma of the liver were examined. But one of these cases showed arterial alteration of its coats and no fibrotic changes were present in any of them.

The rarity of the occurrence of primary carcinoma of the liver renders these cases of especial interest. This is the more true, since there has been so much written concerning the relation of cirrhosis to primary cancer of the liver. Many authors have emphasized the presence of cirrhosis in this type of cancer in a large percentage of the cases reported.

Winternitz,¹ after quoting a number of writers who had presented tables showing the large number of carcinomata which had been associated with cirrhosis says: "This table is of interest, since it points out first what a large number of cases of cancer of the liver are associated with cirrhosis and secondly the tumor may occur in normal and diseased livers. In a tremendous percentage of cases the liver presents an ordinary type of cirrhosis."

It is generally agreed that the cirrhosis precedes the neoplastic formation where these two are associated. The tumor however brings about pressure atrophy directly and necrosis of the hepatic parenchyma through its excessive vascular involvement, and in this way a fibrosis may result secondary to the tumor growth. This is important since in a few cases those areas of liver uninvolved by tumor growth are likewise free of cirrhosis. Whether a cirrhosis may develop secondary to the tumor growth is uncertain but there is no doubt that the cirrhotic process is exaggerated as a result of this. That cirrhosis is more frequently associated with cancers arising from the liver-cells than with those arising from the duct epithelium.

In the series of 4 cases studied by me the cancer arose in 2 cases from the epithelium of the bile-ducts, and in 2 cases from the liver-cell epithelium. There was no cirrhosis in any of the cases. In one of the patients, 9 years old he was too young of course to have developed cirrhosis from the usual causes.

So whatever may be the cause of primary carcinoma of the liver neither vascular changes nor fibrosis could be charged as a causative factor in these 4 cases.

PRIMARY CARCINOMA OF THE LUNGS

The very respectable series of 4 cases of primary carcinoma of the lungs were examined. Owing to the rarity of the trouble, or seeming rarity I felt I was fortunate in finding 4 cases put at my disposal for study in the Laboratory of Pathology of the Ohio State University. A report of these cases has already been prepared for publication.

None of these cases had any vascular changes nor lymphocytic infiltration. But one of them was associated with fibrosis. This one was an epidermoid carcinoma, apparently taking its origin from the bronchial mucous membrane.

An interesting question at once arose as to how squamous epithelium forming the cancer could come from the ciliated cylindrical epithelium of the mucous membrane lining the bronchial tubes. The answer comes from the belief in the metaplasia of one type of cell of a tissue into another type of the same tissue.

Virchow in 1854, propounded the theory of the metaplasia of cells of any type into cells of other types. Metaplasia occurs only within certain limits. Epithelial tissue can be converted into other forms of epithelial tissue one form of mesoblast into another form of mesoblastic tissue.

Adler in his monograph says: "The transformation of one sort of epithelium into another usually of cylindrical or cuboid epithelium into squamous epithelium as has been found in many kinds of inflammatory processes" is well known.

The theory of persisting and abnormally dispersed germinal centers and remnants while it cannot be disproved, is not necessary for the explanation of the so-called metaplastic transformations.

Haythorn observes: "During the study of a case of unresolved pneumonia, one field was found which contained two medium-sized bronchi, the mucosa of which was replaced by granulation tissue covered by stratified squamous epithelium. Then as many as twelve bronchi were found which showed a like condition. He concludes: 'Our find-

Adler. Primary Malignant Growth of the Lungs. Trans. R. Med. Soc. J. Med. Research. 41 p. 513.

ing in a measure agree with Schridde's idea in so far as they show that the metaplastic cells are newly formed cells and that they come from the growing layer. They seem to contradict the necessity of the presence of embryonic rest as they could hardly have been so numerous and simultaneously to set up the process in several different bronchi.

Of the 4 cases of primary carcinoma of the lungs examined by me, 3 were upon the right side and 1 upon the left.

One of these cases, No. 60, is an epidermoid carcinoma of the lung was in a man 60 years old who had been a very heavy smoker of the strongest tobacco. He had worked in a melting work where he inhaled very strong fumes of irritating gases. The clinical history of his case was one of tuberculosis without however ever having found tubercle bacilli which had been sought for some fifteen different times. The point of interest in this case so far as it concerns this study are the history of irritation over a long time, presence of a distinctly fibrous condition of the lung attacked and the metaplasia of the tumor cell into a squamous type.

From the fact that this case was diagnosed as I understand as tuberculosis of the lung clinically, it is done in most cases of cancer of this organ it may prove on more careful pathological study after death that primary cancer of the lungs is not so rare a disease as is now thought to be. We know already that some cases of cancer of the lungs are mistaken for sarcoma or that organ.

Fig. 1. A thickened artery in an epidermoid carcinoma of the lung.

OBSERVATION ON LYMPHATIC INFILTRATION

Different workers ascribe a protective influence to the presence of lymphocytic infiltration. It is believed their tendency is to inhibit the new epithelial invasion. Their habers above quoted refer to Fitch's experiment on the behavior of cancer development in mice after bleeding them which it was claimed stimulated the blood-forming organ to an extent that increased the resistance to cancer after inoculation. Their habers lay great stress upon doing many things that stimulate the blood-forming organ to prevent the recurrence of cancer after operation because he feels that poor blood supply to a part is a causative factor of the disease.

Fig. 7. Thickened artery from the terina of organ of the cancerous age.

not alone that, but also that there is a predisposition to cancer which is partly overcome by this increased blood formation and activity produced by bleeding Biers hyperræmic treatment and the injection of certain glands as the thymus the spleen and the uterus which he claims results in producing a leucocytosis that is detrimental to epithelial penetration. This is in keeping with the experiments of Loeb on the development of cancer in mice under varying influences of internal secretions. He says: "It appears probable that with the co-operation of hereditary conditions all those internal secretions are factors in the origin of cancer which initiate or sustain continuous or periodic growth processes. In other cases mechanical stimulation of growth may take the place of chemical stimulation and again in others a combination of both may be present."

These two sets of factors are sufficiently strong to determine to a great extent the frequency of cancer in mice.

Bearing upon the importance of lymphocytes as a protective influence against the development of sarcoma in rats which coincides with similar conclusions reached upon lymphocytes in cancer by Fischers quoted above Murphy has conducted some interesting experiments on the heteroplastic tissue grafting on rats from a mouse sarcoma. He found that in 10 rats which had been subjected to the influence of X rays for a

certain time sufficient to destroy the lymphatic leucocytes the tumor grew. On the contrary when the grafting of the same sarcoma was undertaken in 10 normal rats no permanent growth took place.

Dr. James B. Murphy and John J. Norton of the Rockefeller Institute made some very interesting experiments on spontaneous mouse tumors. He removed these tumors from 32 mice. He then placed these tumors aside for the moment and subjected the animal operated on to a regulated dosage of X ray treatment that was known to stimulate growth of the lymphocytes. Then the tumors were replaced in the animals in another position. The result was that 50 per cent of the tumors grew slowly and 50 per cent failed. There were 2 per cent of recurrences in the old sites of the tumor.

The next experiment was on two control series of mice likewise affected.

First control: Twenty nine tumors were removed from as many mice and returned into the same animals only in another region without any treatment of the animal or the tumor. 96 per cent of the tumors grew and 48 per cent recurred in the old site.

Second control: Ten spontaneous tumors were removed from mice and the tumors subjected to a similar dosage of X rays as the original experiment. The tumors were then returned into the groin of the animals. The result was 100 per cent of growths and 40 per cent recurrences in the old site.

SUMMARY

1. I have not found the various old age conditions of endarteritis, acellular connective tissue or fibrosis to have been present in all cases of cancer examined.

2. In the study of the various abnormal conditions present in my control series of non-malignant uteri, sclerosed vessels were found without carcinoma.

3. Many uteri with normal vessels showed the presence of cancer-cell infiltration.

4. Many cancerous uteri had only normal connective tissue consequently without fibrosis.

5. Inasmuch as so many of the non-cancerous uteri showed the so-called old age conditions, one would expect to find cancer in them more frequently if they are a positive factor in the development of cancer.

6. The same may be said of the ovary, where it is quite common to find sclerotic changes in the vessels and fibrosis in the stroma in the cancer without the patient having developed cancer.

7. Certain precancerous conditions do not necessarily develop into cancer. This is notably true in smokers' burns, some of which heal though simulating cancer. The epithelium in these cases simply piles up without infiltrating the tissue beneath.

8. Lymphocytic infiltration, even when present, varied greatly in amount. This was true not alone of the cancers but also of the various tissues used as controls; in some cases being very pronounced in others quite light

in amount. It was especially marked in the rapidly growing carcinomata.

CONCLUSIONS

1. Of the 206 cases of carcinoma of all organs and regions examined, 103 showed arterial obstructive changes. This gives us substantially an equal division between endarteritis, 50.06 per cent, and normal vessel.

2. Fibrotic changes were present in 116 cases, 57 per cent.

3. Lymphocytic infiltration was present in 85 cases, 57 per cent.

4. That endarteritis and the anatomical changes of old age cannot be looked upon as a constant factor in the production of cancer is shown by the fact that normal vessels were present in almost half the cases.

5. The same holds true of fibrosis or even acellular connective tissue without fibrosis.

6. Lymphocytic infiltration, while present in less than half of the cases, plays a role that is protective rather than etiological.

7. That certain biochemical factors of a local or internal and general type are probably responsible for some cases of cancer.

This study was made in the Pathological Laboratory of the Medical Department of the Ohio State University through the courtesy of Dr. Ernest Scott, Professor of Pathology. Dr. Jonathan Forman, Instructor of Pathology, was my constant associate in carrying on this study. Mr. Carl Hugger, Assistant in the Department, made the photomicrograph. To all of these I am deeply grateful.

RUPTURE OF THE GALL-BLADDER

ITS CAUSE PREVENTION AND TREATMENT

BY W. W. GRANT, M.D., DENVER, COLO. DO.

WELL authenticated cases of rupture of the gall bladder from pathological conditions are few and deserve always the consideration of surgeons and internists.

Traumatism to the abdominal wall may well excite rupture of a distended diseased gall-bladder just as a similar blow to the lower quadrant might well aggravate a diseased condition of the appendix or a cystic growth, promoting or causing perforation.

The usual condition predisposing to and causing perforation is an infection of the bladder usually of long standing. The acute phlegmonous condition is in itself not primary but secondary to a mild, but steadily progressive pathological condition from micro-organisms, usually the colon and typhoid bacilli and streptococci, finally resulting in gangrene.

The progress and course is similar to that of the appendix, but not so rapid. Gall stones will generally be found in these aggravated cases which result in gangrene and empyema.

These conditions are the result of ignorance, neglect, and delay. The internist may not have appreciated the importance and significance of a clinical history; consequently the surgeon has not had an early opportunity to relieve the condition by operation.

Prevention of infection must depend primarily upon healthy dietetic and living conditions and adequate elimination of intestinal toxins. Typhoid fever predisposes to gall bladder as it does to appendiceal infection.

Prevention of perforation or rupture must depend upon early operation. If this had been the rule in the past fifteen or twenty years, we would hear less now of cholecystectomy which is fast becoming a fad.

Every novitiate and many who are not, seems to feel that he is not up-to-date unless in the swim of the latest surgical innovations. These innovations, in the realm

of the unknown but safely experimental fields, appeal strongly not alone to the progressive surgeon but more to that class of surgeons and physicians who pay in cash for business and are not much concerned about the pathological conditions.

Past experience should inculcate lessons of value and of wisdom as in the popular and much abused operation of gastro-enterostomy for real and doubtful ulcers of the stomach and duodenum, and quite regardless of the important question of pyloric stenosis—the one condition demanding operation that admits of no debate.

I may be pardoned for introducing reports of two cases which are worthy of comment, if not also of record.

CASE. J. C. M., aged 5, farmer by occupation, was operated on in 1903 for gall-stones—several being removed. The gall bladder was drained and the wound or fistulous tract discharged bile for nearly a year before completely healing. The patient remained quite well until the spring of 1904 when stomach dyspepsia recurred. This gradually increased until the night of October 2, 1904, when acute symptoms of perforation attended with severe pain, chill, and fever were suddenly manifested. I saw the patient next morning and operated immediately. It was disclosed that in the former operation, the fundus of the bladder was sutured to the abdominal peritoneum, which was a common procedure at that time, but now justly abandoned.

There was a rupture in the fundus and extravasation of small quantity of pus but limited by omental adhesions. There was no general peritonitis. A smooth round stone as large as a large pecan nut was removed and probably as a small stone was overlooked in the previous operation. It was lodged in dilated cystic duct and without difficulty removed through the bladder.

The bladder except a small part at the seat of perforation was not gangrenous. This was resected with a small piece of omentum and the bladder pouched and drained. The wound healed perfectly in no month and the patient has been perfectly well since. He had no jaundice. The unsatisfactory progress after the previous operation was doubtless due to the presence of the stone removed in the second operation.

Fig. 1. Gall bladder showing point of rupture.

It might be asked why the gall bladder was not removed in such a case. I would answer that in the absence of thickened rigid gangrenous wall there is no necessity for its removal but some good reasons why it should not be. Even killful urgeon overlook the presence of small stones in the bile ducts. What happens in such cases when the bladder is removed. The stone is too large to pass the ampulla or papilla. A second operation sooner or later becomes a necessity. Every surgeon recognizes the increased difficulties if not danger also of secondary operation on the ducts due to adhesions and the destruction of natural guides and landmarks. It is furthermore easier and safer to drain the gall bladder than it is the ducts. There is another objection to cholecystectomy. Interstitial pancreatitis is believed to be due to infection from the bile passages and the most effective treatment of such cases is drainage through the gall bladder. If the gall bladder is removed the matter is needlessly complicated and the treatment more doubtful and difficult.

If not the presence of the gall bladder as a receptacle and temporary reservoir for the bile worthy of consideration as serving some useful purpose.

If the infection is easily remediable by a less radical procedure then it seems to me that cholecystotomy should be the operation of choice. It should be remembered

Fig. 2. Reverse side of the specimen (Fig. 1) showing the substance of the liver.

that cholecystomy does not remove the constitutional diathesis and intestinal toxæmia which exist in infections and gall stone disease.

CASE. Mrs. M. widow, aged 52, living in comfortable circumstances. She had occasional attacks of gall stone she bore several years which had increased in frequency and severity during the year 1915. On the fourth day of last January she consulted me as to her condition. I urgently advised immediate operation as the character and acuteness of the attacks of colic with local manifestations of disease indicated impending danger from perforation and sepsis. She positively and abruptly declined consideration of an operation. On January 11 she sent for me at night. She had been suffering severely all day and evening from a violent and persistent attack of colic. She was vomiting frequently. The abdomen was generally distended and the walls rigid. Notwithstanding my decided opinion that she was suffering from general septic peritonitis due to perforation of the gall bladder she refused to go to the hospital or to submit to operation. In three days she died from septic peritonitis and paralytic ileus.

I made a post mortem which revealed some omental adhesion and a pint of extravasated bile in the right kidney fossa. There was no pus in it and none in the small gall bladder which was contracted around a single round stone the size of a large olive.

I removed with the gall bladder a portion of the attached liver tissue.

Examination showed a small gangrenous area half an inch long and one fourth inch wide with a perforation of the diameter of a slate pencil (indicated by arrow in the photograph picture Fig. 1). On the reverse side of the specimen (Fig. 2) in the substance of the liver will be seen a light colored and firm stone the size of a small pecan nut. This might not have caused trouble and would not have been discovered or suspected in an operation. It was probably in a branch of the hepatic duct.

This patient's life was a needless sacrifice in refusing operation before the last attack and declining the only chance in the beginning of the fatal illness.

There could be no doubt as to the diagnosis and the necessity for operation. The very limited gangrene of the gall-bladder was doubtless due to the pressure and irritation of the stone finally resulting in ulceration and rupture.

Gall bladder infections are common and for

a long and indefinite period do not usually give rise to serious illness even in the presence of gall stones.

More consideration should be given to the early clinical history and to the conditions which predispose to infection.

The condition is curable only by operation and with early diagnosis and prompt cholecystostomy gangrene will not be seen often. The mortality will be exceedingly small without the use or necessity of cholecystectomy.

PUERPERAL GANGRENE OF THE EXTREMITIES

By ARTHUR STEIN, M.D., F.A.C.S., NEW YORK

Visiting Gynecologist, German Hospital; Adjunct Visiting Obstetrician, Harlem Hospital

PUERPERAL GANGRENE OF THE EXTREMITIES

ONE of the most serious and intractable complications of the puerperium and incidentally of pregnancy consists in puerperal gangrene affecting the lower and sometimes the upper extremities. The importance of this menace to childbearing women is plainly illustrated by the reports of 76 authentic cases in the literature, including 5 cases of gangrene after gynecological operations. The disease is however fortunately far from common. The occurrence of two instructive cases in his personal experience led the author to make a careful study of puerperal gangrene and the literature on the subject.

In view of the gravity and gloomy prognosis of the condition it seems advisable to bring the entire subject from pathogenesis to therapy to the attention of the medical profession in general and of gynecologists and obstetricians in particular. The prompt recognition of incipient gangrene is the only safeguard against a fatal issue or at best a marked mutilation of the extremities.

The author's first patient a young woman of twenty years with gangrene of the right leg following abortion recovered after amputation below the knee. The second patient died of exhaustion with dry gangrene of both feet and lower legs after labor at term.

CASE. Abortion, curette gangrene of right leg, amputation recovery.

R. R., 20 years of age, admitted to the Harlem Hospital New York on June 9, 1915. The patient was in the best of health and appeared to be an exceedingly normal and strapping young woman. The heart and lungs were normal, the menstrual history normal, the urine normal. Temperature on admission was 101° and pulse 100. *Physical examination.* Some slight bleeding from vagina, cervix adnuit, one finger uterus about three months pregnant, dense and parametria perfectly normal. *Differential diagnosis.* Threatened abortion (infection).

Shortly after admission she aborted, three months fetus. There was foul odor from the fetus as well as from the vagina. The temperature on the next day dropped to normal only to rise again on the same evening to 101° and 102°. The patient continued having a temperature between 101° and 102° for the next six days with no pains, however, and no other symptoms. On the seventh day after an examination by me it was decided to curette the patient as the uterus was still enlarged and soft. There were numerous grayish white superficial ulcers around the cervix. These ulcers were covered with a mass of whitish membranes. After the curettage by which some placental tissue was removed the whole interior of the uterus as well as the cervix was irrigated with tincture of iodine. This was repeated for the next seven days. Even after the curettage the temperature did not drop entirely but kept between 101° and 102°. On June 13, 7 days after the curette the patient began to complain of pains in the right leg and three days later that is on June 16 in 10 ten days after the curettage the right leg and foot began to swell, became cold, and showed violent bluish discoloration.

Fig. 1. Gangrene of the right leg.

tion. The pulsation of the femoral artery was not to be felt and the patient extremely painful in the thigh.

On June 5th the sensitive leg pained but the patient remained in bed. On June 6th a painful nodule appeared in the thigh. The foot was cold and numb. There was no pulsation in the radial pulse. The patient died on June 10th in the thigh.

It suddenly became known that the patient was gangrenous. It was highly swollen and black. The patient was highly sensitive with pain in the right thigh. The lungs and liver were normal. The heart was normal. The patient died on June 10th in the thigh.

The whole process became more pronounced and the line of demarcation more distinct so that on July 27, in spite of all conservative treatment, amputation had to be performed below the knee. The patient being otherwise in perfect condition recovered in due time. The heart had always been normal and several blood cultures showed no growth. Especially no hemolytic streptococci were found.

The Wassermann test was negative. The result of the histological examination was as follows. The specimen consists of the foot, one-third of the leg and the thigh. There is an ulcerated area at the external malleolus which exposes the peroneal tendons and extends over the dorsum of the foot. Section of the foot shows that the skin and superficial fascia in the plantar region are entirely necrotic. On the dorsum the

muscles are also necrotic. The patient died on June 10th in the thigh. The patient was highly sensitive with pain in the right thigh. The lungs and liver were normal. The heart was normal. The patient died on June 10th in the thigh. The patient was highly sensitive with pain in the right thigh. The lungs and liver were normal. The heart was normal. The patient died on June 10th in the thigh.

This case is of interest because so far as I could find in looking over the literature it is only the fourth case on record of gangrene following abortion. Andérodia has published the case of a right leg becoming gangrenous after an abortion in the sixth month and ending fatally. The second case published by Béguin and Andérodia occurred in a young woman in whom both legs became gangrenous and the right leg had to be amputated. Here also death occurred. In the case reported by them all findings showed that there was a vegetative endocarditis.

Fig. 1. H. Lilienthal's case. Post-operative gangrene of feet.

present. In Oke's (Simpson's) case the left hand was affected.

CASE 2. Labor at full term, forceps delivery, sloughing of perineal sutures, dry gangrene of both feet and lower legs, no operation, death, no autopsy.

L. F., 29 years old, 1-para, was admitted to the Harlem Hospital, New York, on June 10, 1905, at full term of her pregnancy in generally good condition. Her family and medical history irrelevant. Heart normal, lungs, normal, other internal organs, normal, urine at time of admission, normal, no edema present. Wassermann negative.

On day of admission the patient was delivered with medium forceps. A second degree laceration was repaired with chromic catgut sutures. Two days after confinement the patient had a temperature of $103\frac{1}{2}^{\circ}$ and slight chill. On examination it was noticed that there were some slight ulcers around the cervix for which the patient received the ordinary treatment, iodine applications and douches. The urine now showed traces of albumin and some hyaline casts. The temperature dropped to 101°

and. On the sixth day after confinement the sutures were removed because the whole area was sloughing.

Ten days after confinement the patient still had irregular temperatures running up to 103° and 104° and even on the eleventh day a temperature up to 105° . She looked like a very sick person although nothing could be detected outside of the local infection. The heart particularly seemed to be in good condition. Twelve days after confinement on June 27 the patient left the hospital against our advice only to return on July 3, that is seven days later in an acute and critical condition.

On her readmission (July 3) the heart-sounds were of good quality, heart not enlarged, but its action rapid rate. The temperature varied between 101° and 104° . The abdomen was held rigid. No distinct masses could be felt.

An examination revealed that both feet symmetrically for a distance of about four inches above the ankles, were discolored, nearly black, and the skin shrivelled. Both feet were extremely tender on touch, cold and in some places showed vesicles filled with a whitish fluid. A diagnosis of typical symmetrical dry gangrene of both feet could easily be made. At about four inches above the ankles on both sides the line of demarcation was well pronounced on July 7, but the patient's general condition did not permit of any operative interference. There was no pulsation of the femoral arteries. She finally died July 19, due to extreme exhaustion and debility. Several blood-cultures showed that there was no general sepsis. It was impossible in this case for us to get an autopsy so we can only guess at the real cause of this symmetrical gangrene.

In both of these cases we have had to deal with a puerperal infection, in the first case of a rather slight nature and in the second much more severe. In the latter case I would like to advance the following explanation of the occurrence of the symmetrical gangrene. A thrombus left the uterus and migrated into the uterine artery and from there into the internal iliac and common iliac artery up to the bifurcation of the aorta where it also occluded the other common iliac artery and by doing so caused the symmetrical gangrene on both sides. This was not the case in our first patient. As can be seen from the description, the onset of the gangrene was rather slow and the gangrene itself of the moist type. This immediately suggests an occlusion of the venous system in the affected limb with the arterial supply still working. I am inclined to believe that the complete venous obstruction was the primary incident

and that the peroneal artery became obstructed only secondarily. It would be wrong to assume that the obstruction of such a small vessel as the peroneal artery could be the only cause of the gangrene of the entire foot and lower leg. I therefore think that for reasons stated above we have to deal in this particular case with an instance of arteriovenous occlusion of the affected area, the venous obstruction being the primary affection.

The following discussion deals with gangrene due to the puerperal state and affecting the extremities. Diabetic gangrene and gangrene due to poisons (*secale cornutum* for instance) are not included irrespective of the puerperium; cases of the latter kind were not uncommon in Italy some years ago. Obstruction of non-puerperal vessels for example in the brain causing puerperal aphasia as in Sinclair's¹ patient is outside of the scope of the present consideration but it is noteworthy that the veins in the lower part of the right leg became thrombotic. Another observation which requires separate mention is that of Schulz² who referred the peripheral gangrene of his puerperal patient to post typhoid anæmia and resulting nutritional disturbances in the central nervous system. There was no evidence of thrombosis. Seidelmann³ reports a case of symmetrical gangrene of the upper extremities after pneumonia in a woman 29 years of age who about three weeks previously had been delivered of twins. As may be seen from the case histories appended to this article peripheral gangrene has frequently followed childbirth after even longer intervals in consequence of septic endocarditis and embolism so that there would seem to be sufficient reason for accepting a puerperal origin.

Raynaud's disease (as is perhaps not generally known) was observed for the first time in a young woman four months after childbirth and since that time (1862) has been reported as occasionally coincident with the puerperium. The disease as described by Raynaud is characterized by the absence of a maternal

appreciable obstacle to the course of the blood whether arterial or venous. According to the description of v. Mehring⁴ a prolonged circumscribed vascular spasm leads first to symmetric discoloration and finally to gangrene with shedding of the affected tissue areas sometimes entire phalanges. There seems to be no reason to doubt that Raynaud's disease may appear as a manifestation of syphilis as well as of other infections. Of special interest from the present viewpoint is the heading of Raynaud's case report as follows: "Local asphyxia of the feet, hands, nose, dry gangrene of the four extremities going on to the fall of many portions of the ungual phalanges, the whole supervening on a recent parturition. Recovery."

The investigations of Buerger⁵ who studied the vascular lesions leading to presenile spontaneous gangrene refer to thrombo-angitis obliterans, the endarteritis obliterans of German writers, a specific disease which must not be confused with the conditions leading to puerperal gangrene of the extremities. There is no reason for assuming that the specific type of infectious organism which he considers responsible for thrombo-angitis obliterans is identical with the pathogenic agent of puerperal gangrene, a condition in all probability due to a mixed infection. The only similarity consists in the development of certain purulent foci strongly suggesting the presence of some specific toxin or more probably some microbial agent. Buerger points out that spontaneous gangrene can occur in the presence of patent vessels and of peripheral nerves in which no significant changes can be detected. In all the examined cases of puerperal peripheral gangrene organic vascular disease was either demonstrable or the impending changes had been arrested by the rapidly fatal termination.

Etiology. Widely scattered among the many millions of births registered in civilized communities statements are recorded concerning complications on the part of the vascular system in form of puerperal gangrene.

of the extremities. Different types of vascular obstruction in form of arterial venous or arteriovenous blocking with or without changes of the heart valves, may all culminate in the clinical picture of gangrene. Puerperal thrombosis was found in 76 of 34951 cases (0.22 per cent) by Klein¹ 25 cases being frankly due to infection alone. Fatal embolism occurred in 4 cases (0.01 per cent). In other words there was one thrombosis in five hundred births and one embolism in nine thousand births. Jaschke² mentions one thrombosis in four hundred births and one embolism in nine thousand births. A very important cause of origin of thrombi is a considerable loss of blood whether due to parturition, operations or other reasons. An abnormal constitution of the blood favoring the onset of thrombosis was described under the name of *thrombophilia* by Mendel.³

Peripheral puerperal gangrene of venous origin is very exceptional although diseases of the veins of the genital apparatus in form of varicose and thrombotic veins are of common occurrence during pregnancy as well as in women who have borne a large number of children. Phlegmasia alba dolens due to obstruction of the iliac veins with periphlebitis and retrograde lymph stasis is an occasional important complication of the puerperium, but rarely if ever terminates in gangrene.

The arterial origin of peripheral puerperal gangrene is by far the most common and is probably always due to infection. In animal experiments on guinea pigs and rabbits in which extensive thrombi were produced under strictly aseptic conditions, not even the slightest tendency to a rise in temperature could be noted by Nakano. This strongly suggests the probability that the very common rise of temperature in thrombosis after childbirth is always referable to infectious causes. Thrombosis of the arteries of the leg might be due to an ascending thrombosis of the uterine artery from its terminal branches at the site of the placenta the thrombosis extends into the common iliac and even into

the aorta, or it may be continued downward into the external iliac, the femoral artery and its branches. The smaller blood vessels sometimes become obliterated through embolic plugs which have become detached from the thrombi in the large arteries. In favorable cases the onset of gangrene is prevented by the establishment of a compensatory collateral circulation.

The cases in which tissue necrosis does not occur until both vascular systems have become blocked and impermeable constitute the group of arteriovenous puerperal gangrenes. In other cases the blood coagulates secondarily in one system due to complete interruption of the circulation in the other. It is sometimes difficult if not actually impossible to decide if a given case is of mixed arteriovenous origin on account of the difficulty of ascertaining if the thrombi found in one system are of etiological importance or have formed secondarily without contributing to the production of the gangrene.

Although the reason still escapes us why in certain cases the septic or toxic process becomes localized in the internal wall of an artery and in other cases in the venous wall or in both the most common cause of puerperal peripheral gangrene is known to be a septic or toxic endarteritis and embolism from diseased heart valves usually occurring in cases of grave puerperal pyemia.

Infection no matter how slight and apparently irrelevant is invariably present and undoubtedly is always responsible for the conditions leading to gangrene of any kind. Childbirth and the puerperium naturally afford numerous opportunities for infection a very common and extremely dangerous avenue being represented by thrombi at the site of the placenta in the puerperal uterus. The ubiquitous streptococcus, often in association with anaerobic microbes has been demonstrated as the infectious agent in some of the examined cases. Not only the bacteria themselves, however but their toxins play an important part probably through lesions of the vascular endothelium which in combination with the altered condition of the blood during the puerperium predisposes to the formation of thrombi. In this connection

the contribution of Eichhorst on gangrene of the arms and legs after scarlet fever and other infectious diseases is very instructive. A retarded coagulation of the blood in puerperal women was recently demonstrated by Kottmana.¹ Mechanical factors, the recumbent position and relative immobility of the entire body also enter into consideration as possibly lowering the resistance against infection through retardation of the vital processes. It is suggestive that the majority of these gangrenes concern the lower extremities although the upper extremities are occasionally involved and in exceptional instances different extremities with other parts of the body may become gangrenous.

According to the fundamental teachings of thrombosis coagulation of the blood results even in the presence of a sufficient circulation whenever the endothelium of the blood vessels is damaged in its nutrition and thereby in its physiological function. Besides septic infection other causes such as a weakened heart action probably play only the part of the last determining factors. Post-operative thrombo-embolism was directly referred by Fraenkel² to septic infection having its entrance avenue at the operation wound and the same is undoubtedly also true for more distant puerperal thrombi which are likewise referable to a focus of infection. Arterial thrombosis is either the result of a preliminary change of the vascular wall or of a change in the composition of the blood or of a combination of both these factors. Changes of the blood itself usually affect the small and medium sized arteries exclusively whereas very large vessels may be blocked in consequence of lesions of their walls through microbes or their toxins. The pathogenic agents may lodge in the arterial intima giving rise to obliterative endarteritis or the germs in the circulating blood may be arrested in the endocardium where they cause an ulcerative endocarditis which in turn leads to embolism and death of the limb or the patient herself.

The extremely variable cause of the obstruction in the arterial and venous system

is best illustrated by the following tabulation adapted from Wornser:

OBSTRUCTION IN THE ARTERIAL SYSTEM

1. *Embolism*. In septic endocarditis (thrombi on the heart valves). Thrombosis of the heart chiefly the auricle the result of septic endocarditis parading embolism in case of a patent foramen ovale. In a woman who has reached the childbearing age (see cases of Wanner (Olivier) 1900).

Interd. Primary (septic and thrombotic endarteritis) secondary (through propagation of inflammation from the adjacent artery).

2. *Thrombosis*. Primary (ascending from the uterine artery or its terminal branches) or secondary (in total interruption of the arterial blood current at the first case).

OBSTRUCTION IN THE VENOUS SYSTEM

1. *Phlebitis*. Primary (septic and thrombotic) or secondary (a) through propagation from a metapneumonia (b) through extension from the uterine vein.

2. *Thrombosis*. Primary (thrombotic) or secondary (interruption of the venous blood current at the first case).

Symptoms. The phenomena of incipient gangrene are identical with those of mechanical obstruction of the blood vessel and naturally vary according to the mode of origin and the path of the infection in a given case. Pain is very pronounced and never absent in extensive vascular obliteration such as lead to peripheral gangrene. Infection usually being the etiological factor the ordinary symptoms of puerperal fever are apt to precede the signs of tissue necrosis. Septic puerperal endometritis is present in the majority of the cases. In milder cases only a rise in temperature will indicate some slight infection. The mode of onset of the gangrenous symptoms will sometimes though rarely suggest the cause and seat of the vascular obstruction. A sudden onset usually points to embolism in the arterial system (dry gangrene) while on the other hand the gangrene may develop very insidiously in the case of a small embolus. The onset of gangrene may be abrupt or gradual also in cases of purely venous obstruction (moist gangrene) so that the rapidity of evolution of the symptoms permits only an uncertain conclusion as to the seat and origin of the obstacle. In a general practical way it may be said that the early appearance of gangrene in the first few days of the puerperium points to an arterial (the most common) origin.

The *manifestations* of puerperal peripheral gangrene do not require a lengthy description. Aside from the severe pain already referred to the absence of arterial pulsation below the thrombus or embolus is an important sign characteristic of the cases of arterial blocking. The sensibility is usually distinctly diminished, while the motility may be preserved. A livid discoloration and a relatively diminished temperature of the affected area add to the probability of incipient gangrene. In cases of venous origin the inflamed veins of the pelvis are often distinctly palpable by the rectum or the vagina due to the existing thrombosis and periphrastic edema.

The two forms of dry and moist gangrene are apt to be combined in the same case, depending upon the rapidity of complete interruption of the blood current and the presence of external factors which favor mummification. Although the intolerable pain subsides as a rule when the gangrene has become established, the patient's general condition now becomes seriously aggravated through the absorption of necrotic tissue constituents. Before demarcation has occurred death may supervene under increasing pulse and temperature especially in cases of arterial obstruction.

Prognosis. The prognosis of puerperal peripheral gangrene is governed in the first place by the timely performance of amputation. Unfortunately amputation is not always practicable on account of the bad general condition, the rapid progress of the gangrene or because the seat of the obstruction is located high up in the aorta. Puerperal peripheral gangrene has accordingly a very bad prognosis as one half to two-thirds of the patients die for we are not able at the present state of our knowledge to prevent such an unfavorable outcome. While the mortality is still deplorably high it has nevertheless been lessened by one half since the institution of modern measures of treatment. The arterial venous or arteriovenous pathogenesis probably have no marked bearing upon the prognosis or the mortality although it appears that the mixed arteriovenous type of puerperal gangrene is credited with the most favorable figure.

Treatment. The treatment of incipient puerperal peripheral gangrene consists of purely conservative measures applying simply to the prevention of thrombosis and embolism by means of elevation of the extremity heart stimulants judicious transfusion and similar measures. The appearance of the line of demarcation is the signal for surgical interference. Although the dangerous symptoms may apparently subside because the organism endeavors to resist the absorption of decomposition products from the necrotic area it is imperative to remove the gangrenous part as promptly as possible for the safeguarding of the patient's life.

The *prophylaxis* is limited to the ordinary aseptic and antiseptic management of all deliveries, strengthening of the general circulation by heart tonics improvement of local circulatory conditions through elevation and gentle massage. When thrombi have formed elevation of the part is the best treatment to prevent their progress. Premature movements favor the onset of embolism and endanger life.

The manifold instructive features of these cases are best brought out by a comparative study of the material in the general literature. The compilation of authentic cases from the literature of the world brings the entire number of observations up to 76 including 64 cases of peripheral gangrene following labor with one personal observation (author's second case) 4 cases after abortion with a personal observation (author's first case) four cases occurring in the late course of pregnancy and 5 cases after gynecological operations which have been added for reasons of completeness. Twelve years ago in 1904 a list of 80 cases was published by Wormser but this contains a number of observations which are not verifiable or do not properly belong under this heading. In order to correct another statement of Wormser's the author wishes to state that Begg's article was published in the *Lancet* in 1870 and not 1876. Inaccuracies along this line are especially common in the French literature where, for example a case is persistently credited to Roux instead of to Rouse, an English contributor to the *Lancet* in 1896. Moreover

Lafond and other French writers cite 4 cases by Simpson and apart from these the observations of Cowan Bottomley (called Bos-somby) and Reid which are precisely the cases reported by Simpson.

The following cases all very old incompletely reported and partly inaccessible in the originals are cited after Wormser¹

CASE 1. Unnamed observer in 154 Rec. period obs. de med. de chir. de Pharm. Par. Vol. 1 p. 149, described gangrene of one extremity twelve days after labor amputation on the same day without noticeable arterial bleeding. The other lower extremity was shortly afterward affected in the same way and the patient died five weeks after confinement. No autopsy.

CASE 2. Latham Med. Comment. 40. 11 163 described a case in a woman between 30 and 40 three fingers of whose left hand gradually became quite painful one week after childbirth and were removed without pain or hemorrhage. The condition recurred about six days later and at the end of another fortnight the part below the wrist were removed. Finally the ulna and radius became loose and were cast off but the patient recovered.

CASE 3. Coctsem Ann. Soc. de méd. le. (and 1835) Puerperal gangrene of upper extremities nose upper lip cheeks also gangrene of the right leg and knee.

CASE 4. Tonnelle Arch. gén. de méd. 1840. Vol. 42. Case of puerperal gangrene in a primipara of 24 developing eight days after delivery in different regions of the body including the anterior portions of the thighs and the heels. Death on tenth day.

CASE 5. P. E. Edouard Raynaud Thèse doct. Paris 1841. Puerperal gangrene of part of both arms cheeks and chin.

The majority of the cases 53 in number concern peripheral gangrene of the lower extremities. The left leg or foot alone was affected 16 times the right leg or foot alone 15 times both lower extremities 15 times. In 3 of the case reports the affected side is not specified. In one instance (Begg's case) both hands both feet, the tip of the nose and portions of the ears were gangrenous. Mau-rice Raynaud's case fifteen is similar to this. In Rouse's first case both legs five fingers and the right ear were affected. MacFar-lane's patient had gangrene of the right leg and right arm and Levers' patient of the left leg and left arm.

Following abortion gangrene of the lower extremities is represented by only three

cases of which one came under the author's personal observation and was followed by recovery. The right leg as in this case was likewise concerned in a case with a fatal outcome reported by Anderodius. In another case (Bégoun and Anderodius) both lower extremities were involved and the right leg was amputated but without saving the patient's life.

Gangrene of the upper extremities a relatively rare puerperal complication is noted in 10 cases five of which concerned both arms one with involvement of the legs one the left and one the right arm. In one instance one finger of each hand was affected in another the fingers of both hands finally in one case there was symmetrical gangrene of the fingers toes and ears. Following abortion there is only one recorded example of gangrene of an upper extremity namely Oles's case (Simpson) in which the left hand was affected.

The rarity of peripheral gangrene during pregnancy is illustrated by the scanty number of corresponding observations on 4 cases. Three of these cases concerned the right leg one (which recovered) with simultaneous slight involvement of the left leg. In the fourth case the little finger of the right hand became gangrenous and was amputated. All these cases occurred in the latter part of pregnancy.

Peripheral gangrene as a sequel of gynecological operations has been reported in 5 cases which for reasons of completeness have also been tabulated. In the youngest patient a primipara of twenty years with severe puerperal infection requiring abdominal hysterectomy both legs were affected by symmetrical gangrene and amputation was performed with a successful outcome. The other four patients elderly women died one with gangrene of the left leg one of the right arm and one with gangrene of one lower extremity which was amputated without saving the patient's life. The gynecological operations which had been performed were laparotomies for ovarian sarcoma multiple or unusually large myoma abdominal hysterectomy and oophorectomy plus appendectomy (Lahenthal's case).

The above figures are given approximately rather than accurately for it will be readily understood that some of the cases belong to more than one group while in others no detailed statements are available.

Arterial obstruction through embolism or thrombosis due to endarteritic changes is especially noted as the cause of the gangrene in 29 cases. Disease of the heart (vegetative endocarditis aortic stenosis thickened mitral valves etc. etc.) alone or in combination with arterial obstruction are noted in 13 cases and persistent foramen ovale in 3 cases. Here it must be emphasized however that many cases did not come to autopsy and are incompletely reported in this respect the observer leaving the cause of the gangrene an open question. Obstruction of both arteries and veins was present in 12 cases Begg's case being doubtful however Venous obliteration alone was apparently responsible in 9 cases (Willcox's case being doubtful) In Schaeffer's case no changes at all were found neither in arteries nor veins. In 3 out of 4 cases of post-operative gangrene it is stated that the arteries were thrombosed.

Very rarely and as a suggestion rather than an assertion a patent foramen ovale is mentioned in explanation of a paradox embolism as in Oliver's first case and in Willcox's case. However Popow directly charges the open foramen ovale with the responsibility for the puerperal gangrene of both arms in his case, which was free from endocarditis. Among the seventy five tabulated cases, thirty three patients recovered and forty died. In two instances (Cowan's second case and Dickinson and Hubert's second case) the outcome is not stated. Only 4 among the 33 cases recovered without an operation (Guthrod's second case Dickinson and Hubert's first case Seidelmann and Schulz's cases).

The presence of an infectious disease was noted in several of these cases. The peripheral gangrene in Schulz's patient developed after premature labor at the end of the third week of typhoid fever. In Seidelmann's case the gangrene followed on pneumonia. Oliver's second patient had pneumonia of the right lung. Pleurisy is stated in one of Cowan's cases.

Puerperal fever and obliterative endarteritis preceded the gangrene in Etienne's case six months after childbirth. Severe puerperal infection necessitating abdominal hysterectomy is noted by Roux de Brignoles and Auriant. Puerperal ulcerative endocarditis as a forerunner of gangrene is mentioned by Baré and du Casel.

General sepsis is mentioned three times and pyemia once in association with puerperal gangrene of the extremities, and Montault's patient suffered from peritonitis with probably general sepsis. In altogether six cases peripheral gangrene occurred in combination with eclampsia. The occurrence of puerperal mania is specially mentioned in two observations.

From the forensic viewpoint, the sporadic occurrence of puerperal peripheral gangrene is very important in so far as it may strike when least expected in an apparently uncomplicated case like lightning from a clear sky. Forewarned is forearmed and the large collection of cases from the literature will serve as a helpful precedent. It is also in this regard that the author hopes to have offered a serviceable contribution to surgical gynecology in supplementing his personal observations with the interesting material which is so widely scattered in the general literature.

Although the co-operation of unfavorable circumstances which lead to peripheral gangrene can hardly be foreseen and prevented, the safety of our puerperal patients will be decidedly enhanced if the possibility of such a formidable complication is kept in mind. That youth, a healthful condition, and a normal labor do not afford protection, is shown plainly enough in the cases embodied in this paper. A thorough knowledge of the predisposing causes and watchful care at the bedside are the only means to check a further extension of the list of peripheral gangrenes due to the puerperal state.

A. PUERPERAL GANGRENE OF LOWER EXTREMITIES

BARÉ and DU CASSEL. Étude clinique sur les embolies de l'aorte et recherches expérimentales sur la production des souffles cardiaques. Arch. gén. de méd., 88, 190.

Woman age 30 years, four and half months after normal birth of her healthy third child was admitted to the hospital on account of indigestion with loss of con-

foot. Amputation of left leg, upper third. Examination of the specimen showed thrombosis of the posterior tibial artery. The thrombus extended upward from the site of the amputation and could be drawn out from the vessel.

CROSSBOROW. Gangrene der forme im Pericarpium. Russk. Vrach. St. Petersburg. 905 VII, 246 Petersburg. med. Zisler 909 XXX, 37.

The author observed case of gangrene of both feet, in the pericarpium, terminating in death. The patient was 42 years, eighteen years of age. Manual extraction of placenta. Left thrombophlebitis. Thirty day post partum gangrene of left foot. Finally death after erysipelas had set in.

COWAN. Cited by Simpson Selected Gynec. & Obst. Works, 87 p. 564.

Patient age 36 healthy and active. Delivered of fourth child, lochia and lacteal secretions were normal. On the morning of the fourth day she had severe rigor, and when soon she was screaming from excruciating pain, referred principally to the upper and inner portion of the left calf which was cold and tense, but not increased in size. This condition extended to the foot, on the forepart of which large spot of ecchymosis appeared, most evident upon the metatarsus and creeping upward to the ankle-joint. The uterus was perceptibly larger than usual. The discoloration had reached half way up the calf of the leg (having a very margin) and was still advancing. The following morning vomiting had begun on the spot first discolored and the patient was rapidly sinking. Death occurred early on the fourth day of the disease and the eighth day after delivery. N. autopsy.

COWAN. Cited by Simpson Selected Obst. & Gynec. Works, 87 p. 564.

Patient aged 5. Ten days after delivery of her first child she was seized with gangrene of one of the lower limbs. The gangrene involved the foot and leg joint. The knee-joint, the patient was greatly exhausted and anxious, but not suffering severely. The limb was amputated at the lower third of the thigh, but not a drop of blood followed the knife. She died the next day of exhaustion. No autopsy.

D. VIER, J. A case of phlegmona dolens, which terminated in aphrodisia of the leg and foot. Lond. Med. Repository 85 XXXII, 45.

The patient 41 years, was suddenly seized with most excruciating pain in the left loin and hip, two weeks after her last confinement. The limb gradually became swollen and very cold, the leg and foot and lower two-thirds of the leg were of dark purple color and distinct line of demarcation formed. In the course of the following week considerable sloughing took place on the lower and back part of the leg, until scarcely anything remained but the bare bones. The author finally removed the limb above the knee. As soon as the vessels were cut across, the blood in the veins was seen to be coagulated, arteries intact. Patient made good recovery.

DECOUVER. Embolie de la partie inférieure d'aorte. Gaz. d. hôp. 880, p. 735.

Primipara, age 22 years, two weeks after normal confinement, was attacked by severe pains in both legs, and examination showed the absence of pulsation in both femoral arteries. Next day appearance of large discolored patch on anterior portion of left knee, followed by other patches on the left calf, and purplish discoloration on the right side. Lower portion of right leg was discolored up to

5 cm. above the malleoli. The condition of the limbs became aggravated in the course of the following days, while the general condition improved until three weeks after the first onset of the pain, the patient had an attack of delirium, followed by fever and died three days later. N. autopsy could be obtained. Judging from the similitude of the appearance of the disturbances in both limbs at once the obstacle must have been situated in the aorta near the bifurcation.

DURLOU. Gangrène du pied droit ayant déterminé la mort un mois et demi après l'accouchement. Progrès méd. 83 p. 3.

Woman 39 years old IV-para, toward the end of pregnancy had sudden pain in the right foot with discoloration and immobility the foot being absolutely cold. After while the foot became black. Ten weeks after the onset of these symptoms she was delivered of dead child. One month after confinement the patient was in very bad condition the foot being black and immovable and the thumb soft to touch. On pressure there was gaseous crepitation. N. edema of the leg. Sugar in the urine not due to previously existing diabetes. Bloody expectorations. Death seven weeks later. On topography the genital organs were found to be normal. In the right upper lung gangrenous pneumonia. Slight thickening of mitral valve heart otherwise normal. Right femoral artery obliterated by thrombus commencing immediately below the bifurcation of the aorta. All the arteries of the right leg also obliterated. The author does not assume an embolus because the heart practically normal.

DUKE JAMES. Cited by Simpson Selected Obst. & Gynec. Works, 8 p. 530.

Patient delivered of first child after protracted labor. Two weeks after delivery gangrene of both lower extremities. Death four days after admission to the hospital. On dissection heart was found to be normal. Beginning about an inch and half above the bifurcation of the aorta, fibrous plug was found which completely occluded the artery and extended along the common iliac, and as far as one or two inches down the external iliac arteries on each side. A prolongation of the plug shut up also the canal of the internal iliac artery on the left side. On the right side the opening of the internal iliac artery was occluded by the obstructing mass occupying the common iliac artery. The femoral and other arteries below were quite healthy and the veins of the limbs presented no special morbid appearances.

EDWARDS. A case of bilateral gangrene of the legs following confinement. Brit. M. J. 93 p. 27.

Patient, woman 38 years old as admitted to hospital two days after normal delivery of her twelfth child. Ten days after admission, symptoms of incipient gangrene made their appearance, the condition becoming aggravated about week later and gangrene simulating more the dry type than otherwise was manifest. Three days later the limb was amputated through the middle of the thigh; well above the external limits of the spreading gangrene. At the end of five days following the operation, loss of circulation was noticed in the right lower extremity and gangrene up to the knee became evident. Patient refused to have the limb amputated, her general condition up to the time of death remained remarkably good. Death took place suddenly about twelve weeks after the first appearance of gangrene. Post-mortem examination showed that the external iliac and the common iliac arteries, as far as the bifurcation of the aorta, were blocked by continuous thrombosis, evidently of some standing.

ESCALIER. Bull. Soc. anat. de Par. 1846 xxi 277

Presentation of specimen from a woman 28 years of age who had died of spontaneous gangrene following her first confinement. After an attack of peritonitis pain was felt in the right leg without signs of phlegmasia alba dolens. Four days later gangrene manifested itself and at the time of the patient's death, on the fifteenth day after the onset of the disturbances the gangrene extended above the calf. At the autopsy the hypogastric veins and several of their branches as well as the right common iliac vein were found blocked by solid gray thrombi adherent to the vascular walls. The iliac artery at its junction with the femoral contained a firm grayish clot which filled the third part of the arterial lumen and became bifurcated at the level of the profunda femora. The findings were suggestive of a partial arteritis due to compression of the femoral artery through an abscess of the iliac fossa.

ETIENNE. Gangrène massive d'un membre inférieure par endartérite oblitérante progressive suite à distance d'une infection puerpérale. Arch. gén. de med. 1900 n. p. 2402

Patient, primipara 26 years of age, forceps delivery. Infection of wound in vulva, puerperal fever, recovery. Some months after childbirth, onset of double phlebitis of lower limbs, type of phlegmasia alba dolens, requiring three months for its cure. About three months after recovery from this phlebitis, vesicle filled with reddish fluid appeared in the anterior portion of the middle third of the right leg. This was soon followed by symptoms of incipient gangrene with discoloration in the left foot. The condition became gradually worse, the patient left the hospital and died about 3 weeks later.

IVISON. Malignant gangrene of both legs following parturition. North Car. M. J. 1889 xvi 49

Patient, primipara 20 years of age. Symptoms of septic infection five days after childbirth with chills and fever. Within ten days she complained of cold feet with intolerable burning pain. Within fifteen days appearance of characteristic dusky hue of gangrene in both feet. The morbid process continued, reaching in the left leg, within three inches of the knee, and in the right leg, three inches above the ankle, before the patient succumbed to pyemia ten weeks after childbirth.

FISHER TH. Double phlegmasia followed by gangrene of the right foot. Lancet Lond. 1898 i 995

Patient 45 years old. XI para. manual extraction of placenta on account of hemorrhage. Deep collapse 4 days after confinement, pains in abdomen and joints, diarrhoea. On the eighth day phlegmasia. Pulse 120 to 130, temperature 40°. On the twelfth day, bluish discoloration of right leg, and diminished sensibility. General condition of patient very poor but improved under stimulants. The toes became gangrenous and were finally amputated.

The author discusses only the influence of marked hemorrhage on the formation of the phlegmasia but does not enter into any discussion on gangrene.

The case is similar to Wormser's first case.

FUSSEL, N. H. Gangrene of leg following labor. Uni. M. Mag. Phila. 1888 i 165.

Patient had injured the great toe of left foot, eczema of knee followed previous to present pregnancy. In eighth month of pregnancy left thigh twice its normal size, covered with "buccinas." Two hours after labor (normal lying child) the limb became livid, there was intolerable itching and burning, the foot was cold and the patient

went into collapse. No amputation on account of bad general conditions. Death.

The author thinks that the popliteal artery was closed by a thrombus, which began to form a few days previous to labor. The slowing of the blood in the artery consequent to labor allowed a complete thrombus in the inflamed point and consequent gangrene resulted.

GOLDENFELD LU. Die Leber Cirrhose der Extremitäten. Inaugural Dissertation. Bonn 1900

Patient 55 years old, normal, lived out of bed the eighth day. On that day a little pain appeared in left foot, the hair on a few days became normal, hair and fat penetrated, odor of pulsation in the popliteal artery. The left thigh was swollen, but not painful. The right leg was highly edematous and very painful. Amputation of left leg below the knee. Recovery.

Diagnosis: gangrene due to embolism. The location of the embolism.

LEITCH, R. O. Gangrene of the limbs. M. N. (Lancet) 1898 xvi 34

Patient, primipara 26 years of age, had many eclamptic convulsions in number and as treated with trypsin. On second day of the eclamptic attacks, a septic state set in, the temperature rose to 102° F., the pulse was 120, the patient was delirious, the urine was bloody, the patient was in a state of collapse. The patient died on the third day. The patient had been in a state of collapse for several days before the onset of the eclamptic attacks. The patient had been in a state of collapse for several days before the onset of the eclamptic attacks. The patient had been in a state of collapse for several days before the onset of the eclamptic attacks.

CASE. XI para. 4 years of age had eclamptic seizures before and after parturition. Patient died on the tenth day of the evening of this day, the temperature had been perfectly normal in the last five days, sudden rise to 102° F.

The left thigh presented a bluish black discoloration of the skin and the temperature was bright red almost to the knee joint. The gangrene and inflammation pressed during the first day but remained limited to the knee and became necrotic. The process lasted over four months under high and antiseptic treatment.

H. GEMMEL. Ueber puerperale Gangraen der unteren Extremitäten. Wien. klin. Rundschau. 90 x 685

The patient, XI para. 4 years of age had myodegeneration of the uterus and secondary retention of the placenta. On ninth day after delivery symptoms of thrombosis in left leg, followed by dry gangrene of the foot and the distal part of the leg. On seventeenth day after childbirth amputation of the lower third of the thigh. Recovery.

Examination of the amputated extremity showed a threatening evident embolism of the bifurcation of the popliteal artery. All the arteries were thrombotic.

V. HOCHSTETTER. Spontane Gangraen beider unteren Extremitäten nach dem Puerperium. Wien. med. Wochenschr. 1883 p. 4

Patient, 24 years old. During the fifth week pains in right leg which became ordematous. During the seventh week post-partum, the patient was admitted to the hospital. At that time the entire foot was bluish black.

pulse in femoral artery not present. The veins were not dilated. Heart and urine normal. Temperature 38.5. During next few days demarcation below malleoli. About 3 weeks after onset of discase pains in left leg which was black up to knee and anesthetic but not anemic. Demarcation of left leg up to height of the knee. Two months after beginning of discase, amputation, on the right side above the malleoli and on the left in the middle of the thigh. A description of the findings of the amputated legs. Recovery.

The author explains his case as follows. Ascending thrombosis of the right tertiary artery and of the hypogastric and external iliac arteries followed by gangrene on the right side then continuation of the thrombosis up to the bifurcation of the aorta and here (1) that point either occlusion of the left common iliac artery or embolism followed by gangrene on the left side, and finally extension of the thrombus up to the renal artery which might explain the existing albuminuria.

LARCIERREUX. Phlébite postpartale. *Gaz Méd* 887 No. 8.

Patient 30 years old III para, normal delivery out of bed on fourth day. On fifth day edema of left leg. Urine and heart normal. Three days later after the first signs of edema on the left leg had subsided edema appeared of the right leg of the abdominal wall and also of the left labium majus. The diagnosis as obstruction of the hypogastric vein and vena cava. About month later coughing, dyspnea and pneumonia in the left lower lung set in, due evidently to pulmonary embolism. One week later marked pains in both legs with discoloration. Sensibility diminished and practically gone below the ankle. Diagnosis as obstruction of the two femoral arteries because no pulsation was felt over them. Death. A topography of the thromboses. All the veins (hypogastric, external iliac, femoral and renal) obstructed by clots. The aorta, the renal arteries, the common iliac, the hypogastric, the external iliac and the femoral arteries, thrombotic.

The author explains the formation of the thrombosis as follows. It started in the tertiary sinuses and as propagated into the renal veins, and thence into the renal arteries either by contact or through the renal capillaries, from the renal arteries the process extended to the aorta and downwards.

LARCIERREUX. Cited in Trousseau's *Thrombose d'agregation*, 880.

The patient, woman 35 years of age, with phlegmasia alba dolens of the right leg, beginning six weeks after confinement and terminating in abscess and gangrene of the calf died one month after admission to the hospital about ten weeks after childbirth. The autopsy showed considerable edema of the lower extremity with extensive gangrene of the calf and the lower surface of the right thigh. The femoral veins contained black clot, becoming less firm and dark in its upper portion. In the iliac veins the clot began to be softened in the center and it reached into the inferior vena cava, as far as the renal veins. In the right renal vein it went process which entirely obliterated the vessel, and another process extended into the left renal vein, blocking it only at its termination. The hypogastric veins were filled with more or less indurated blood-clots.

LARCIERREUX. Cited by Simpson, *Selected Obst. & Gynec. Works*, 871 p. 530.

Patient suffered from an attack of acute rheumatism during pregnancy and died after a few days' illness following delivery. During this period it was discovered, that

there was no pulsation in the arteries of the left arm; and subsequently the same absence of pulsation was observed in the left inferior extremity. Local symptoms of gangrene were manifest in the left hand and left foot. At the post-mortem examination, mushroom-like vegetations were discovered on the valves of the heart, and in the arteries of both the affected extremities vegetations were found obstructing the lumen while the veins contained phlebotiths.

LEVENKOWSKY. Ueber die Entstehung von Gangraen der Extremitaeten nach der Geburt. *Gaz. lek.*, 19.

N. 3.

Gangrene of the foot on seventeenth day of septic puerperium after complicated labor. A thor claims the gangrene was due to embolism of the dorsalis pedis artery.

N. utopay.

Primipara, 8 years of age. Diarrhea for long time before birth of a dead premature child. Ulcers paronychia paronychia vaginitis paronychia. Right foot became swollen on the fourteenth day after delivery gangrene three days later. Patient was now admitted to the hospital, where she died at the end of twenty four hours.

LEVENKOWSKY. De la gangrene des extremités chez les accouchées. *Gaz. hebdom. d. sc. m. d. de Bordeaux*, 90.

xxii.

The patient, I para, had thrombosis and suffered from eclamptic attacks during labor, was delivered by forceps of a dead child. On tenth day phlegmasia alba dolens, on right side four days later onset of gangrene of right leg requiring amputation two months later. The operation was followed by recovery. Examination of the amputated extremity showed the presence of clots in the arteries, which presented endarteritic changes caused by streptococci.

MACFARLANE. Cited by Simpson, *Selected Obst. & Gynec. Works*, 87 p. 530.

The obstruction of the artery occurred suddenly ten days after the patient was delivered naturally and easily of her fifth child. At that time she began to complain of acute pain and numbness in her right arm, which, with slight intermission from opiates, etc., continued till her death at the end of three weeks. No pulsation could, from the first or subsequently be felt below the middle of the brachial artery. A week after this arterial occlusion in the upper extremity a similar change took place in the right thigh, accompanied with acute pain. This ended in a great measure four or five days after when unequivocal indications of gangrene showed themselves, commencing at the toes and extending to the knee. On dissection the aortic valves were found to be covered with numerous vegetations. The aorta was dilated and studded with thrombotic deposits. At the points of obstruction (viz. the middle of the brachial, and the commencement of the lower third of the femoral arteries) fibrous clots were found, which completely closed these vessels.

MANDEL. Ein Fall von Gangraen der beiden unteren Extremitaeten im Wochenbette. *Wien. med. Wchnschr.* 90 II, 307.

Primipara, 3 years of age, spontaneous labor fever from second day on, infected perineal wound. Venous thrombosis began on seventh day on the left side, on eleventh day on right side, leading to gangrene on the thirteenth day. Whereas on the left side the gangrene was limited to a few superficial areas, amputation above the knee had to be performed two and one-half months later on the right

side the operation showing that all the arteries and veins were blocked. Favorable healing of the stump. Recovery.

Monk. Cited by Simpson, Selected Obst. & Gynec. Works, 1871 p. 535.

Patient, I-para, was prematurely delivered. Three weeks afterward pains like those of neuralgia were experienced first in the right leg and then in the left. Seven weeks after delivery there was sudden pain and tenderness in the left groin. At this time a loud systolic murmur could be heard. Some days subsequently the pulse in the right arm became suddenly arrested and no pulsation in the right femoral and iliac arteries could be felt. The arterial pulsation in the larger vessels of all the extremities had ceased with the exception of the left arm. Finally gangrene of the great and two next toes of the left foot set in ten weeks after delivery. The patient died a few days afterward.

Autopsy. Thrombi in bifurcation of aorta, common iliac and external iliac arteries vegetative endocarditis.

MONTAUD. Accouchement naturel, péritonite engorgement des membres inférieurs avec symptômes de phlegmasia alba dolens mort. Présence de pus dans les veines des jambes. J. compl. d. sc. méd. 1831 lx, 11.

Patient a woman 3 years of age on day following normal birth of a healthy child, was attacked by peritonitis. Twenty days after the delivery the left thigh became swollen and very tender on pressure. The swelling increased in the course of the next following days and a week later had invaded the right lower extremity under the same symptoms. The gangrenous patches extended into the depth of the tissues and the patient finally succumbed to exhaustion five weeks after delivery. Autopsy showed phlebitis with the presence of pus and of whitish false membranes in the veins of the legs.

OLIVER. The Gangrene of the leg in puerperal women with severe pain in and analgesia of the affected limb. Lancet Lond., 1866 ii 15.

CASE 1. Patient 33 years old I-para, in good health. Labor and early part of puerperium normal. Two weeks after labor patient became weak and paresis of the right arm and facial nerves developed. There was a slight aphasia. The right leg was intact. On the following day the paresis had disappeared, whereas marked pains in right leg set in. The same evening the small toe of the right foot became gangrenous. The lower two-thirds of the leg showed a darkish blue discoloration. The next morning the temperature was 98.8° pulse 64. The foot was nearly bluish black the leg showed livid discoloration and was cold and anesthetic up to about 4 inches above the knee. Passive motion of the leg and pressure on the big arteries and veins was extremely painful. No albumin in urine heart normal. The gangrene progressed rapidly without a marked demarcation. Two days later amputation was performed about 5 inches above the knee. Recovery. The popliteal artery and vein of the amputated limb were thrombotic. (Whether the thrombi were tightly adherent to the walls of the vessels is not stated.)

CASE 2. Patient 45 years old II para, normal labor. About four days later pneumonia of right lung six days later quite suddenly marked pains appeared in right leg, the leg showing no abnormal condition. Examination showed a marked systolic murmur of mitral valve. The whole left leg was infiltrated. Nothing was felt in the abdomen. The right leg was pale cold swollen anesthetic. The skin was purplish blue. Over the aorta, there was a slight systolic murmur. The foot and leg up to

about 3 inches below the knee were entirely anesthetic and cool. As apparently the gangrene spread rapidly amputation above the knee was performed. Five days after operation patient was decidedly better but she died three weeks after operation. Autopsy.

Examination of amputated leg showed embolism of popliteal artery extending into its two branches all the veins contained coagulated blood (thrombi).

This second case is remarkable because the endocarditis developed so to say under the physician's eyes (similar to Werners first case). The thrombosis of the veins is also of a secondary nature. It is clearly a case of general sepsis similar to Winckel's case.

In Oliver's first case it is also remarkable that the gangrene developed so quickly that in 4 days after the onset of the first pains amputation of the thigh had to be done. On the fourteenth day after confinement general debility and paresis set in due in Oliver's opinion to embolism of one of the arteries of the brain whereas the obliteration of the popliteal artery was consequent upon the action of a poison causing clotting of the blood.

The heart was normal. If that was the case there is only one explanation of this case similar to Wanner's case and that is that there was an open foramen ovale i.e. an embolism from the side of placental insertion. The embolus is not thrown from the right auricle into the right ventricle and from there into the pulmonalis but finds its way through the open foramen ovale into the left heart and divides itself there into different parts. Small particles were thrown into the left carotid and gave rise to the embolus in one of the arteries of the brain whereas the bigger part of the embolus is thrown into the cruralis where it forms a total occlusion of that artery. The clots in the veins are apparently of secondary nature as there is in the clinical picture no signs of any phlebitis.

It is hard to give a satisfactory explanation for the extremely quick progress of the gangrene.

OVERSIEDE. A case of phlegmasia dolens, terminating in gangrene of the foot. Amputation, Recovery. Med. & Surg. Reporter 1875 xxxiii 127.

The patient, a woman 34 years of age, developed gangrene of her left limb about three weeks after the birth of her eighth child. Severe pain in the limb which was swollen and tender especially along the course of the femoral vessels was felt first on the ninth day after con-

confinement and fortnight later evidence of gangrene was seen on the inner side of the heel rapidly spreading and invading the entire foot. Amputation as performed at the lower third the swelling disappearing rapidly and the patient less than two months later was discharged with good stump, and health completely restored. At the time of the operation the large arteries were found completely obstructed.

PHILLIPS, R. Gangrene of the legs during the puerperium. Death. *Middlesex Hosp. J. Lond.* 1901, 111, p. 70.

Apparently normal puerperium for seven days after birth of patient, third child. Well nourished woman of 30. One week after childbirth, alarming attack of sudden severe pains shooting down the left leg, with general collapse. Signs of femoral embolism were found on examination. Condition of the leg did not improve, and four days later the toes began to become discolored. Light days after the first attack patient had similar attack in the right leg. Her condition from now on got worse, the feet and legs gradually passing into state of dry gangrene. Gradually the gangrene extended half way up the left thigh and above the right knee in its upper part being moist and offensive. Patient gradually weakened and finally died fifty nine days after labor. She was never in condition to permit operation. The uterus and heart were normal.

REID, ROWEN. Cited by Simpson. *Selected Obst. & Gynec. Works*, 87, p. 564.

Patient had previously borne large family. Last labor was easy for it came premature. Child born dead. On the third or fourth day subsequent to delivery fever supervened, followed by swelling of the left leg. Such was attended by great pain and suffering. In the course of two or three days gangrene set in and she died ten days after delivery. N. torrey.

ROBERT, L. R. Gangrene complicating puerperal mania. *Lancet*, Lond. 1896 II, 375.

CASE. Patient 3 years old I-pars. T. weeks after normal confinement admitted to London County Asylum on account of mania. Physical condition good. Eight days after admission to the asylum pains in feet and fingers which were cold, anemic and anesthetic. The next morning all the toes and the five fingers of one hand and the right ear were gangrenous (Raynaud disease). N. fever. The lochia which are suppressed for while became very offensive. The gangrene of the feet progressed slowly. Temperature up to 101. On account of impending heart failure amputation of both feet, on the right side at the lower third of the leg and on the left side after Syme method. On the thirty first day after amputation temperature on both stumps new gangrenous spots which were cauterized. Recovery. Left the asylum after eight months in mental normal condition.

CASE 2. Patient 37 years old, V-pars. Confinement three months previously. Admitted for very pronounced maniacal condition. Two weeks after admission, there set in very rapidly progressing gangrene of the right foot and leg. Amputation after two weeks from onset of symptoms in lower third of the thigh. Examination of the amputated limb showed very extensive thromboses of the veins and endarteritis of the larger arteries.

It is a question whether this second case can still be classified as a case of puerperal gangrene since the symptoms set in three

months after confinement, but the possibility of a connection cannot be denied. The case also is of interest because it was shown microscopically that both the arteries and the veins were diseased.

SEITZ, Ueber Uterineleisgangnen im primären febrilen Wochenbett. *München. med. Wchnschr.* 1903, 31, 963.

Patient, primipara suffering from gonorrheal infection. Puerperium wasafebrile but with constant slight elevation of the pulse rate. After moderate femoral edema and symptoms of crural phlebitis, without obtaining thromboses of the principal veins, rapidly progressive edema made its appearance in the left foot, followed by extremely severe congestion. Onset of gangrene three days later associated with establishment of severe coagulative hyperemia of the left foot. It inflammation of the right saphenous vein.

Amputation of the left foot. Examination of amputated portion showed cutaneous gangrene as far as Lafranc articulation. It circumscribed excoriations of the malleoli. The muscular gangrene concerned the vastus and the inner calf muscles. The arteries and veins were entirely free from thrombi or emboli. The congestion of the right foot subsided after the amputation of the left leg. Recovery.

SEITZ. Gangrene d'un membre inférieur pendant les suites d'accouchement. *Prov. méd.* 1903, 10, 303.

Gangrene of the left leg in previously healthy VII para of 35 years. Three eclamptic seizures before child birth, which was normal, and three seizures after delivery. Rapid recovery. Delirium and hallucinations on the fourth day. Two days later patient suddenly complained of severe pains in both legs especially the left. The end of three weeks this leg was cold, rigid, anesthetic up to four fingers width above the knee. N. palpation was palpable in Scarpa's triangle. On the eighth day after delivery the left leg was purplish in color and presented large blister on the external malleolus, on the twelfth day large blister appeared on the posterior surface of the thigh. The condition gradually became worse, the palms extending to the entire abdomen, and the patient died 3 days after confinement. N. autopsy could be obtained, but the bacteriological examination of the thrombotic blood in the left femoral artery showed the presence of streptococci and staphylococci.

TATE, MAGNUS A. Puerperal gangrene. *Am. J. Obst.* N. Y. 1903 LXV.

Seven and one half months pregnancy eclamptic. One day after confinement, patient had sleepy feeling in left foot, afterward both legs became gangrenous. Death 3 days after confinement.

VAN GHELEN. Puerperal thrombus, endocarditis, dry gangrene. *T. N. Y. Path. Soc. Med. Rec.*, 1893, Sept. 240.

Patient 3 years of age, 30 twenty days after childbirth, as attacked with severe burning pain in the right foot and leg. Discoloration of the skin, extending a few days later to the ankle, with complete blackening of the skin over the lesser toes. The patient lingered in great pain for five weeks and then died. The right femoral vein contained clot completely filling the vessel and partially organized. The right femoral artery contained firm laminated thrombus.

WÄNGBER, R. Zwei seltene Wochenbettkomplikationen. München med Wchnschr 1895 p 74.

Woman 31 years old II para normal labor. Four days later pains and oedema of the left thigh, the groin was red, tender and very sensitive. Slight rise in temperature several times during next few days. On the twenty second day of the puerperium a sudden collapse set in with marked dyspnoea. At the same time there were marked pains in left calf temperature rose. Small vesicles began to form on left thigh and right leg. No pulsation was felt over left popliteal artery. On the thirty first day the entire left leg was swollen and the skin discolored to a bluish black from the middle of the leg downward. The toes and the skin of the plantar pedis were entirely dried out and black. The line of demarcation established itself during the next few days. About the middle of the leg the mummification made further progress. Two months after confinement amputation. Normal recovery.

The anatomical examination showed an embolus of the popliteal artery with continuation of the thrombus to the tibialis antica and postica arteries. The heart was intact. The author therefore explains the embolus of an artery of the lung (collapse and dyspnoea on the twenty second day of the lying in period) on the one hand as well as the embolism of the big artery of one of the lower limbs through an open foramen oval (paravalvular embolism) (similar to Oliver's first case).

WILLCOX, F. A. A case of tedious labor followed by double phlegmasia alba dolens and gangrene. Lancet Lond 397 p 85.

Patient 44 years old I para. Anæmic otherwise healthy. Tedious labor patient rather weakened. I cepa delivery with laceration of perineum. First two weeks normal (temperature up to 99.5). On the evening of the sixteenth day very marked pain in left leg phlegmasia. Elevation of left lower limb. On the twentieth day the second toe of left foot became discolored this discoloration next day continued up to the ankle. On the twenty third day temperature rose. Patient excited. Left foot next day was very cold anæsthetic and black color. Very pronounced pains. On the twenty seventh day the abdomen was rather distended the pulse small and irregular these peritoneal symptoms subsided but on the thirty third day a phlegmasia appeared also on the right lower extremity. On the thirty fourth day the patient died due to her extreme feeble condition. Necropsy. Author gives explanation of the origin of the gangrene.

It seems that this gangrene was caused *only* through extensive thrombosis of the veins. This would be similar then to Winckel's case.

The same is illustrated also by an observation on a tuberculous boy of 18 years reported under the following title: Reyt. Étude sur les gangrènes d'origine veineuse un cas de gangrène du pied droit et de la partie inférieure de la jambe droite par oblitération veineuse avec intégrité des artères chez un sujet cachectique. Thèse de doct. Paris 1897.

WINCKEL, F. Die Pathologie und Therapie des Wochenbettes. 3rd ed. 98 p. 32.

Patient 33 years old II para. During the night of the second and third day after normal labor chills and

temperature up to 100. Pains in abdomen. The veins of the right thigh became inflamed. Reddish discoloration and a line spreading from the reddish and painful arteries all over the right leg. A small nodule on the left calf remained stationary. On the seventh day after labor a nodule was noticed on the right distal malleolus. Three days later the whole foot felt thick. It was found to be anæsthetic and a bilateral discoloration. From the next day pain was diminished. The gangrene progressed and small red heads appeared on the middle of the leg. Mort gangrene. Death followed on the sixteenth day.

A topographical dissection with dissection of the foot and leg. All the muscular vessels contained fibrinous masses. Same findings in the popliteal and crural veins up to the groin. At that point a white putrid thrombus was found in the crural vein. The arteries were empty. Besides these findings there was a purulent pleuritis and peritonitis (streptococcal abscesses of the lining lymphatics of the tricus valve of the spleen).

In Winckel's case there was *only* a thrombophlebitis involving practically all the veins of the leg. The arteries were empty. This case like Wilcox's case shows that gangrene can be due *only* to very extensive obliteration of the vein without an embolus or arterial thrombosis.

WILCOX, F. A. A case of tedious labor followed by double phlegmasia alba dolens and gangrene. Lancet Lond 397 p 85.

Patient 44 years old I para. Anæmic otherwise healthy. Tedious labor patient rather weakened. I cepa delivery with laceration of perineum. First two weeks normal (temperature up to 99.5). On the evening of the sixteenth day very marked pain in left leg phlegmasia. Elevation of left lower limb. On the twentieth day the second toe of left foot became discolored this discoloration next day continued up to the ankle. On the twenty third day temperature rose. Patient excited. Left foot next day was very cold anæsthetic and black color. Very pronounced pains. On the twenty seventh day the abdomen was rather distended the pulse small and irregular these peritoneal symptoms subsided but on the thirty third day a phlegmasia appeared also on the right lower extremity. On the thirty fourth day the patient died due to her extreme feeble condition. Necropsy. Author gives explanation of the origin of the gangrene.

WILCOX, F. A. A case of tedious labor followed by double phlegmasia alba dolens and gangrene. Lancet Lond 397 p 85.

Patient 44 years old I para. Anæmic otherwise healthy. Tedious labor patient rather weakened. I cepa delivery with laceration of perineum. First two weeks normal (temperature up to 99.5). On the evening of the sixteenth day very marked pain in left leg phlegmasia. Elevation of left lower limb. On the twentieth day the second toe of left foot became discolored this discoloration next day continued up to the ankle. On the twenty third day temperature rose. Patient excited. Left foot next day was very cold anæsthetic and black color. Very pronounced pains. On the twenty seventh day the abdomen was rather distended the pulse small and irregular these peritoneal symptoms subsided but on the thirty third day a phlegmasia appeared also on the right lower extremity. On the thirty fourth day the patient died due to her extreme feeble condition. Necropsy. Author gives explanation of the origin of the gangrene.

The anatomical examination showed an embolus of the popliteal artery with continuation of the thrombus to the tibialis antica and postica arteries. The heart was intact. The author therefore explains the embolus of an artery of the lung (collapse and dyspnoea on the twenty second day of the lying in period) on the one hand as well as the embolism of the big artery of one of the lower limbs through an open foramen oval (paravalvular embolism) (similar to Oliver's first case).

In this case the endocarditis without causing any symptoms was probably the cause of the embolism. (The endocarditis is not

essential to bring about an embolism as is proved in Winckel's case.)

ZIMMER, E. Ueber Gangraen im Puerperium. *Ergebn. d. Gynaek.*, 9, 4 p. 25. (This case is identical with that reported by Guggenberg, *Verhandl. d. deutsch. Gesellsch. f. Gynaek.* xv Kongr. B., 3.)

Patient 5 years old II-para. Four days after confinement slight mastitis on left side. Five days later patient out of bed. Seven days later recurrence of mastitis. On following day pains in both legs especially in calves and toes. Heart normal. Bluish spots on dorsal and plantar surface of right foot, and total anæsthesia up to about cm. above malleoli. On the day following also bluish discoloration of left foot but its circulation was gradually re-established, with marked hyperæsthesia. Demarcation of gangrene on right foot.

According to Zimmer patient was discharged without amputation being performed whereas according to Guggenberg's above-mentioned communication the gangrenous part of the right foot was amputated. The author thinks that in this case the gangrene was due to ergotism because as he says the symptoms appeared simultaneously in both legs. I am rather inclined to believe that here too we have to deal with an infectious process (mastitis being present).

B. PUERPERAL GANGRENE OF THE UPPER EXTREMITIES

BILLROTH. *Chir. Klin.*, Berl., 87, p. 470

Spontaneous gangrene of forearm of puerperal origin. Patient was woman 25 years of age near the end of her sixth pregnancy. Four days before an easy labor at term, she felt pain in her left hand, and two days later the entire upper extremity was swollen, up to the axilla. Seven days after the onset of the pain the fingers became blue then black, and the gangrene rapidly invaded the forearm. Amputation of the limb, at the middle of the arm, on the twentieth day after the appearance of the pain. Complete recovery within one month after operation.

Billroth did not see this case himself, but from the description believes it to have been due to embolism of the ulnar artery probably referable to endocarditis, with vegetations on the aortic valves. He states that he observed an entirely analogous case also originating during pregnancy of spontaneous gangrene of the leg in Zurich.

COMMANDEUR and GOWNET. *Phlébite double des membres supérieurs causée de l'infection puerpérale*. *Soc. Chér. de France*, 909 Oct.

Bilateral phlebitis of upper extremities in puerperium. Patient II-para, 30 years of age. In third week following childbirth, sudden fever, pain, and thickening in area of veins, first of left arm then also of right arm, with oedema from finger-tips to axillæ. The lower extremities were intact. Repeated pulmonary embolism. Death on twenty-eighth day after delivery. A autopsy showed arm-veins up to the elbow as well as both cephalic veins filled with extensive blood-clot.

DICKINSON and HUBERT. A case of Raynaud's gangrene in connection with parturition. *T. Clin. Soc.*, Lond., 54, xxxi, 6

CASE. Patient 42 years old, VII-para. Previously had symptoms of Raynaud's disease in the fingers of both hands. "After immersion in cold water her fingers would turn white and numb and then blue and painful. Two days after last confinement all the finger tips and both thumbs became itchy and painful. Discoloration followed and finally turned bluish-black. A few days later

the toes were attacked the same way. Rough systolic murmur. Finally line of demarcation formed and some of the fingers were allowed to fall off, no operation being performed. (This is pure case of Raynaud's disease.)

CASE 2. Patient 44 years old IX-para, last child still-born. Three months afterward symmetrical gangrene of fingers, toes, and ears. No subsequent history.

These two cases as well as Case 15 in Raynaud's original thesis and Begg's case, show a more or less close connection between symmetrical gangrene and parturition.

FRANKEL, L. Ueber spontane puerperale Gangraen beider oberer Extremitäten. *Monatsschr. f. Geburtsh. u. Gynaek.*, 903 xlii 78

The patient was primipara 24 years old. Spontaneous labor followed by persistent fever. On the twelfth day of the puerperium no arterial pulsation could be felt along the entire left arm, which was colder than normal, lightly discolored and swollen. Two days later the pulse had also entirely disappeared in the right arm. Death on the next day (15th). No autopsy. The clinical course of the case indicated pure septicæmia, without a clinically demonstrable localization. No lesion of pelvic organs. Complete blockage of the arteries of the upper extremities.

OSTERLOW. *Gynaek. Gesellsch. zu Dresden* reported in *Zentralbl. f. Gynaek.*, 90, N. 7, 440.

Report of case of bilateral embolic mastitis. Patient was admitted to hospital in state of pronounced septic infection and promptly succumbed to the disease. She had moreover an abscess in the right lobe of the thyroid gland, and gangrene of the third phalanx of the fourth finger of the right hand, and the fifth finger of the left hand.

POROW. Gangraen der oberen Extremitäten im Puerperium. *J. f. Geburtsh. u. Gynaek.*, 909, No. 8 (Russian). *Zentralbl. f. Gynaek.*, 90, No. 47, 1459.

Primipara age 36 years, came under observation on eleventh day of puerperium, after normal and easy labor left arm was discolored almost up to elbow covered with vesicles, cold, without sensation or motion; right arm was similarly changed on anterior surface of the forearm and in region of the fourth, fifth, and in part of the third finger. Rise of temperature had begun since fourth day of puerperium and patient noted first red, then purplish spots, with pain, in the arms, as outlined above. Lines of demarcation began to form on twentieth day after delivery and the left arm was amputated at the upper third of the humerus. Resection of gangrenous portions of right arm followed by transplantation of skin on the granulating surface. Patient made good recovery. Old emboli were found in the left radial and ulnar artery and a similar embolus was assumed in the right ulnar artery. The arterial walls were entirely unchanged. The veins were entirely permeable and empty. There had been no cardiac symptoms at any time, and there was no evidence of endocarditis. The emboli were therefore assumed to be derived from the uterine veins, hence they reached the general circulation through patent foramen ovale.

SCHULZ, R. *Mittl. u. d. med. Abt. d. k. k. Krankenh. zu Braunschweig*. *Deutsch. Arch. f. klin. Med.* 84, xxxv, 86.

Primipara, age 5 years, premature labor (7 months) at end of third week of typhoid fever. Soon afterward, after severe collapse, paronychia and tingling sensations first in feet then in finger tips, with swelling of legs. In part

superficial, in part deep gangrene of circumscribed skin areas in exactly symmetrical localities of the legs, upper and lower arms and chest. The fingers and toes were not gangrenous. Moderate pain in the affected limbs. No evidence of thrombosis, no thrombotic strands could be palpated. Recovery. The condition is referred by the observer to post-typhoid anemia and resulting nutritional disturbances in the central nervous system.

SEIDELMAN Deutscher Zeitschr. f. Nervenh. 1904 xvii, 114.

Case of symmetrical gangrene of the upper extremities after pneumonia in a woman 29 years of age who about three weeks previously had been delivered of twins. Although the attack of pneumonia is credited by the observers with the responsibility for the onset of the gangrene he admits that puerperal etiology cannot be altogether excluded in view of the relatively recent childbirth.

ZARODNIK Ernst Ueber Gangraen im Puerperium. Ergebn. d. Gynaek. 9 4 252

The following case is identical with that briefly reported by v. Guggenberger in Verhandl. d. deutsch. Gesellsch. f. Gynaek., xv Cong. vol. II, 23

Patient 26 years old, II-para. Three days after normal confinement chills and high temperature. On the ninth day very pronounced pains in the whole of right arm, edema of same. A few days later cessation of pulse in ulnar and radial, no sensibility. First livid discoloration, finally bluish black color. Small vesicles on epidermis. Marked odor. Blood culture, hemolytic diplococci Gram positive. On fourteenth day after confinement systolic murmur. On seventeenth day after confinement amputation in the middle of the humerus for gangrene. Subsequently patient went through a very serious pyemia but finally left the hospital cured.

Examination of amputated arm. The brachial artery is patent about 5 cm. below its bifurcation. There is an embolus to be found in the radial as well as in the ulnar artery occluding these two vessels entirely. Bacteriological examination of these emboli shows diplococci, Gram positive.

Author thinks that in this case the embolism was due to an existing endocarditis.

C. GANGRENE AFTER ABORTION—UPPER AND LOWER EXTREMITIES

ANDRÉOUDAS. Gangrène des membres inférieurs pendant les suites de couches. Ann. Soc. d'obst. de France 190 159

Author's second observation (Lacouche's case). Patient, IV-para 4 years of age with aortic stenosis, abortion at the sixth month. Two weeks later sudden severe pains in right groin, examination showed diminished temperature of leg and absence of femoral pulsation. Gangrene of the entire leg followed, leading to death on the tenth day. No autopsy.

BÉLOUX and ANDRÉOUDAS. Infection post-abortive endocardite végétante, embolie gangrène d'un membre inférieur amputation, mort. Rev. mens. de gynéc. obst. et ped. de Bordeaux, 1907 p 10

The author's observation concerned a young woman 26 years of age who after early abortion was attacked about two weeks later by extremely severe pain of sudden onset especially marked in the right lower extremity but also involving the left. Hazy and purplish discoloration especially of right leg; this was cold more particularly at the level of the foot, no arterial pulsation in pedal and

femoral artery, on the left side the pedal artery was practically not felt, but the femoral pulsated normally. Progressive gangrene first appearing in the distal part of the right foot and on the right leg rapidly tending to a considerable portion of the foot and distal aspect of the leg as far as below the knee. The thigh remained warm and of normal color as far as three finger widths above the knee. Amputation at middle thigh (radial rest of pulsation in the left femoral artery with appearance of large ecchymoses up to the knee.

Death 5 days after birth. Autopsy showed the presence of vegetative endocarditis affecting the mitral valve and through the pericardium the myocardium giving rise to the emboli and repeated gangrene.

OLKE. Cited by Simpson. Selected Obst. and Gynec. Works. 18 1 p 541

Patient age 24 years. Abortion about 3 months. On the 11th day she was seized with severe headache, giddiness, dimming of vision and vomiting. No great was the interruption to the work that she could distinguish the hand of a mirror. The fingers of the left hand felt as though they were dead and were extremely painful. On the following day the dimming of vision continued and there was intense pain in the fingers of the left arm which at length became cold and insensible to external impressions. The rest and the tips of the fingers were discolored.

On examination no pulsation could be felt in any of the arteries of the arm above the affected hand but the subclavian was distinctly felt pulsating above the clavicle. There was perceptible disturbance of the function of the heart and embarrassment of the respiration. This patient eventually recovered with the loss of gangrene only of the interphalangeal of the thumb and fingers of the left hand. In three days the power of vision was restored. The pulsation never returned in the obliterated arteries of the left arm but the arm itself gradually regained its sensibility and returned plumpness. Heart normal.

D. GANGRENE DURING PREGNANCY

POWELL. Gangraena sporadica digiti minimi manus dexterae in gravida enucleata. Bericht d. k. k. Kran. krankenst. d. polib-Spitalung in Wien 1884 p 412

Case of spontaneous dry gangrene of the little finger of the right hand in a young otherwise healthy pregnant woman. Patient a woman 28 years of age eight days before admission to the hospital was suddenly attacked by pain with reddening of the right little finger, the redness promptly subsided and the finger turned black. On examination this entire finger was seen to be black, mummified and dry up to the metacarpophalangeal joint. There was a distinct line of demarcation of the boundary of the gangrene. Two days later the gangrenous finger was removed. The entire process had no injurious influence on the course of the pregnancy, which was at the seventh month when the patient first came under observation.

JARDINE. A case of gangrene of the leg from thrombosis during pregnancy. J. Obst. & Gynec. Brit. Emp., 1903 March p 90

Primipara age 24 years came under observation in last month of pregnancy. In good health until eight days ago when pain appeared in the right foot and leg with spasms and tingling sensations. The pains progressively increased in severity and at the time of admission to the hospital the right foot and leg were pale, cold and bloodless. No pulsation in artery of leg, weak pulsation in popliteal

space. Two days after admission forceps delivery of hydrocephalic child which died 10 hours later. Numbness could be felt in the femoral artery and the thigh was very cold to the touch. Vesicles formed and the line of demarcation made its appearance just above the knee. High amputation of thigh. All vessels of the stump were thrombotic. The amputation flap became gangrenous and was destroyed. Pain, coldness, and absence of pulsation were likewise noted in the left leg a few days, but the phenomena subsided again. The cause of the thrombosis could not be discovered, the cardiac condition could not have caused it, is the author's opinion.

MUTZLER. Handb. d. Geburtsh., vol. II p. 935.

Patient 34 years old, 1 para. 7 five years previous ulcers crabs on right leg. Eight weeks before confinement chills and fever. Eight weeks later new chills and pains in right leg. Finally gangrene set in on right foot and leg. This condition the patient was admitted to the clinic. Forceps delivery. Death 4 days later.

Post-mortem examination showed no thrombi in the larger vessels but old thin thrombi were found in the muscular veins of the legs. Nothing is stated about the arteries.

SWAYNE. Gangrene of the thigh during the seventh month of pregnancy. T. Obst. Soc. Lond. 584, xiv. 5.

Swayne relates case occurring during the seventh month of pregnancy. The disease came on after long journey and attacked the integuments and muscles over the space of the size of a man's foot on the upper and inner third of the right thigh. The symptoms had existed about four days before the occurrence of premature labor but were not very severe until after delivery when they became much intensified and proved fatal early on the third day. There was no injury, wound, or erysipelatous inflammation to account for the occurrence.

E. GANGRENE AFTER GYNECOLOGICAL OPERATIONS

CHATEL. Des Gangrènes en général et en particulier des gangrènes des extrémités. Thèse de doct. de Paris, 904.

CASE. Gangrene of right arm following laparotomy for removal of sarcoma of the left ovary. Patient woman of 35 years of age. Right hand and forearm became cold and painful on third day after the operation, and on the eighth day the arm was amputated, the upper third (level of surgical neck). Not a drop of blood escaped from the gaping brachial artery in the stump. The vessels were ligated, although the condition was evidently hopeless, the arterial obliteration involving the axillary or the subclavian. Death four hours after the operation. Autopsy.

CASE. Death through gangrene of the entire left extremity following an abdominal operation. Patient woman 50 years of age. Difficult removal of multiple fibroma complicated by double aneurysms. On the evening of the operation, the patient began to complain of pain in the heel, promptly ascending to the root of the thigh. The entire limb became cold and lifeless. By the next morning the leg presented all the characteristics of arterial gangrene. There were no unfavorable symptoms on the part of the abdomen. On the following night the patient complained of some stiffness in the other leg and she died on the morning of the third day. Autopsy findings. Complete thrombosis of the arteries of the left limb, reaching as far as the aorta and extending also into the hypogastric artery. On the right side, clot connected

with the above clot at the bifurcation of the aorta) occupied the common iliac, but topped at the bifurcation of the iliac arteries, which were permeable. No perforating.

JESSITT. J. Obst. & Gynec. Brit. Emp., 904, vi, p. 8.

Gangrene of the leg, after abdominal hysterectomy for myoma weighing 25½ pounds. The leg became cold soon after the operation and the line of demarcation formed above the patella. Amputation of the leg fourteen days after the first operation. Death four days later. Autopsy showed thrombosis of the external iliac and nephritis. Each had not been present at the time of the first operation. The gangrene had been dry throughout.

ROUX DE BEUX. Les Accidents Gangréneux symptomatiques des extrémités consécutifs à une infection purulente. Marseille, 1900, xiv, 577.

Jahrbuch f. Chir. u. g. 21, p. 236.

Abdominal hysterectomy for severe puerperal infection. On the day of the operation bluish discoloration of the ends of the first three toes in both feet, followed by development of asymmetrical gangrene. Amputation after line of demarcation had formed. Recovery. Patient is primipara 16½ years of age. The hysterectomy served as the aseptic procedure in this case of non-localized septicemia.

ADDENDA

Through the great courtesy of Dr. Howard Lillenthal of this city I am able to add an interesting case of his to my paper and want to take this opportunity of expressing my appreciation to him. His case is the fifth of gangrene after gynecological operations and the seventy-sixth in the whole series.

H. Lillenthal's case. Post-operative embolic gangrene of fingers amputation of fingers.

Mrs. R. H., 8 years old, entered Mt. Sinai Hospital on December 26, 1905. Temperature 99.5, pulse 100, respiration 14. Thirteen years before she had had post-operative sepsis. Five years before she had been operated upon at Mt. Sinai Hospital for dysmenorrhea. Four months before her appendix and right ovary had been removed in a hospital in another city and ventral suspension had been done. At the same time an exploration of the upper abdomen had been made. The patient stated that gastrotomy had been performed but as to this there is some doubt.

Menstruation had begun when the patient was 4 years old and for 3 years before admission had been very painful.

About ten days after the last operation there was sudden pain and tingling of the ends of the fingers of her left hand two days later the skin of the hand and fingers began to change color then dry gangrene of the fingers and of the end of the thumb developed. Her physician told her that he found sugar in her urine. There was loss of 51.30 pounds in weight during the past month. The patient was in a very feeble and run-down condition on admission to the

HAR MORIAH HOSPITAL

Chart Case 1

convulsion which lasted fifteen minutes the pulse became imperceptible, and at 11 a.m. the child died.

Much to my regret we were unable to obtain a post mortem examination but from past experience, I have not the slightest doubt, that this was an authentic case of heatstroke.

At this point it is only proper to call attention to the fact, that during the first half of September 1915 New York City was suffering from a heat wave of unusual length and severity. September 10 in particular is featured by the *New York Sun* as being almost the hottest day of the year.

On the same day I was invited by Dr. Eli Moschowitz, Pathologist to Beth Israel Hospital, to witness the autopsies of two patients who died with unexplained high post-operative temperatures. The autopsy did not reveal anything unusual, and certainly nothing to explain the high temperatures. It was the pathologist's opinion, that both patients died of post-operative heatstroke. I am greatly indebted to Dr. Harry E. Isaacs, Attending Surgeon to Beth Israel Hospital, for his permission to incorporate a brief history of these two cases.

CASE 2: Ike R. age 38 was admitted September 6, 1915. During the preceding six years the patient had been suffering from frequent attacks of pain in the right lumbar region, which radiated downward and inward. Lately similar attacks occurred upon the left side also for two days prior to his admission to the hospital, the patient vomited very frequently and his bowels moved only with the aid of enemas. The urination was not increased in frequency.

On physical examination there was elicited tenderness on deep pressure over the entire abdomen particularly marked in the vicinity of the umbilicus. In other respects the physical examination was of no importance.

The patient was operated upon by Dr. Isaacs September 8, at 5 p.m. Abdominal incision was made through the left rectus, five inches in length. The omentum was adherent to the sigmoid flexure. On separating the adhesions the omentum was found to contain an abscess; this portion of it was therefore resected and a cigarette drain was inserted to the sigmoid flexure. The wound was closed in layers.

Even before the operation the patient had been running a temperature up to 103° F. therefore a post operative rise to 103° F on the following morning was not very surprising. However, barring an intercurrent drop of two and one-half degrees for a few hours in the afternoon, the temperature continued to rise reaching 107.8° F at 6 p.m. of the following day and shortly thereafter the patient died (Chart 2).

A careful autopsy was performed a few hours later and following anatomical diagnosis established. Chronic congestion of lungs, with acute hypostasis chronic congestion of liver chronic congestion of spleen chronic congestion of kidneys localized peritonitis in the region of the sigmoid flexure. In the absence of any findings explanatory of the high temperature, the pathologist arrived at the diagnosis of post-operative heat stroke.

CASE 3: Gusale G. age 30 was admitted September 6, 1915, to Beth Israel Hospital. Patient was operated upon one year ago for cholelithiasis no relief however was obtained on the contrary the operation was followed by jaundice which had not existed before. Operation September 8, 1915, by Dr. H. E. Isaacs. Exposure of the common duct through a five inch longitudinal incision in the right hypochondrium. Enormous adhesions were encountered, which made the exposure of the duct somewhat tedious. The common duct was found to be distended and to contain several calculi after incision of the duct these were removed. Drainage by two tubes, one leading into the hepatic duct and the second into the common duct toward the papilla of Vater.

 H.S.

BETH ISRAEL HOSPITAL

Admitted *Sept 6*

Chart 3 Case 2

After the operation the temperature began to rise slowly but steadily it reached 103° F next morning 104° F in the evening 105° F next morning and a few hours later the patient died with a temperature of 106° 8' F (Chart 3)

An autopsy was held on the same day and the following anatomical diagnosis was made by the pathologist. Recent choledochostomy with recent localized peritonitis brown pigmentation of the myocardium chronic congestion of the liver with fatty infiltration acute hyperplasia of the spleen chronic pancreatitis chronic congestion of the kidneys with parenchymatous nephritis

In view of these findings and in view of the fact that the patient died thirty six hours after operation with a temperature of 106° 8' F it was the pathologist's opinion that the cause of death was heatstroke.

I have been on active summer service at Mount Sinai Hospital regularly every year from 1899 to 1914 and have often had the impression that during particularly hot weather some of my patients suffered from a mild insolation however I find in my histories only the following case reported as an

actual and undoubted case of post-operative heatstroke

CASE 4 Benjamin A. Russian age 34 was admitted to Mount Sinai Hospital August 7 1900. His principal complaints were cyanosis and pain of the foot he has had a number of intractable ulcers in the vicinity of the toes, resulting progressively in their total loss. He was treated at that time for Raynaud's disease but there is no doubt that he was suffering from what we now designate as thrombo-angitis obliterans.

The pain was so severe that I finally acceded to the wishes of the patient and consented to amputate the leg. Amputation August 11 1900 through the knee joint by the Ssabanjeff method. The patient did not react well from the operation and he was also noisier than usual. One and one half hours after operation the temperature rose to 104° F four hours later the temperature was 108° 2' F. The patient was in a stuporous condition the skin was hot and dry. Insolation was suspected therefore an ice pack was ordered. The pulse became imperceptible and was apparently uninfused by active stimulation. The patient died seven hours and forty minutes after operation with a temperature of 106° 5' F (Chart 4)

Autopsy twenty hours post mortem showed all

BETH ISRAEL HOSPITAL

Admitted

Chart 3 Case 1

the organs normal with the exception of chronic parenchymatous nephritis of slight degree. Examination of the brain showed a marked congestion of the vessels upon the surface of the brain. Some increase of the cerebrospinal fluid, with dilatation of both ventricles. Cut section of the brain showed a congestion of the vessels. The sinuses of the dura were found to be normal. At that time we looked upon these findings, as distinctly corroborative of our diagnosis of post-operative heatstroke.

The summer of 1900 must have been a particularly severe one as regards heat and humidity because the only medical article published with post-operative heatstroke as its subject dates back to that year. I refer to Gibson (1) who reports two cases of post-operative heatstroke which occurred during the preceding summer in his service at St. Luke's Hospital. The history of these two cases is the following:

CASE 5. Walter O. C. age 3 was admitted June 1, 1900, with an attack of appendicitis of moderate severity. Temperature 101°F pulse 120. Immediate operation in gas and ether anesthesia.

gangrenous appendix was found and extirpated gauze draining partial suture of wound. Immediate recovery was good until the afternoon of the next day when the symptoms were such as to cause the gravest anxiety. The temperature was 104°F pulse 48 and very poor countenance pinched color ashy grey-blue skin hot and dry some delirium. The condition of the wound was perfect. Ice packs and alcohol sponge baths reduced the temperature whereupon the delirium also ceased and was followed by a refreshing sleep. The case thereafter terminated in a prompt convalescence.

CASE 6. Charles Van E. was admitted to St. Luke's Hospital with an acute pericarditis. The patient was extremely obese weighing more than three hundred pounds. Heart action feeble and intermittent. Temperature 104°F. Immediate operation evacuation and drainage of a huge abscess, and extirpation of gangrenous appendix. One and one half hours after operation the temperature rose to 103°F. Ice packs and an ice coil to the abdomen and head brought the temperature down to 100°F thereafter the temperature fluctuated between 100°F and 101°F and was very probably due to absorption from the abscess cavity. Two weeks later the patient was considered to be convalescent when he suddenly died. Autopsy showed the death to be due to the cardiac condition.

Gibson read the paper at a meeting of the Surgical Section of the New York Academy of Medicine November 1, 1900. The paper as reported in the *Journal of the American Medical Association*¹ created considerable discussion as is evidenced by the following additional case reports:

CASE 8 and 9 Johnson reports a case in a child, of excision of a cicatrix from the lower lip with a single skin graft. The temperature of the operating room on that particular day was 10° F. Within a few hours after the operation the temperature of the child rose to 105° F. death occurred the same night. A few days later Johnson had two similar cases but this time prompt treatment with ice packs was instituted and was followed by recovery.

CASE 10 Brewer reported a case of extirpation of the tonsil for carcinoma. The temperature of the operating room was 90° F. Two hours after operation the temperature of the patient rose to 104° F. and the pulse to 150. There was also delirium. Prompt treatment with ice packs was followed by recovery.

Crandon and Ehrenfried state that they have seen three cases of post-operative heat or sunstroke. The history of the following case only is given:

CASE 11 Boy 23 years of age was admitted with an acute appendicitis of three days duration. Temperature 103° F. pulse 100. The street temperature in Boston on that day was 100-101° F. with excessive humidity. Immediate operation a gangrenous appendix with a large abscess was found. The condition of the patient was very good on leaving the operating table. One hour later however there was a sudden rise of the temperature to 104° F. and the pulse to 180. The skin was dry and red, the tongue and lips were dry. The eyes were glistening, the patient was irrational. Ice packs brought the temperature down to 100° F. in twenty-four hours thereafter convalescence was normal.

I am indebted to Dr. Cunniffe for the history of the following unpublished case of post-operative heatstroke:

CASE 12 Miss C. while visiting in the country, was suddenly seized with severe general abdominal pains which soon became localized in the right iliac fossa. Six hours later she was seen by her physician who diagnosed an acute appendicitis and referred the patient to Dr. Cunniffe for immediate operation. The patient was transferred to a sanitarium, a distance of eight miles in an open automobile without adequate protection from the sun, on July 4, one of the hottest days of the summer of 1912.

THE MOUNT SINAI HOSPITAL

FIGURE 1

The patient was operated upon at 4 p.m. Intermuscular incision was made. On incising the peritoneum a small amount of serous fluid was found. A swollen and congested appendix was extirpated, the wound was closed without drainage. The patient was returned to her room at 4:40 p.m. in good condition. Two hours later the temperature of the patient rose to 100.5° F. A diagnosis of heat stroke was made and prompt treatment with ice packs instituted. The temperature remained very high throughout that night. On the following day it ranged from 101 to 102° F. and did not reach the normal until July 6. The wound healed by perfect primary union.

The literature dealing with the symptom complex caused by exposure either to the direct rays of the sun or to high degrees of artificial heat is exceedingly voluminous. The references appended to Steinhauser's monograph *Verensystem und Insolation*⁴ cover over twenty-two closely printed pages and in addition the statement is also found that only the newer literature approximately that after 1850 has been considered. However even with such a wealth of material

Berlin, Aug. Hirschwald 1912.

there exists no unanimity regarding the disease. After a very careful study of the more important contributions to the subject I have arrived at the conclusion that our knowledge as to the etiology symptomatology pathology and treatment of the disease is in a chaotic state. If this is true of heatstroke or sunstroke in a general sense a disease so common as to be at times epidemic or endemic in nature, how much more likely is it to be true of that small and selected group which particularly interests us at present, namely post-operative heat or sunstroke. Altogether as is seen, there have been reported in the literature only the two cases of Gibson a few more were mentioned in the discussion of Gibson's paper. Three additional cases were mentioned casually in a textbook dealing with post-operative treatment. Thanks to the courtesy of my colleagues, and from my own experience I am able to add five more cases. In other words, a total of barely twelve cases scattered through more than fifteen years, is all that is available for study. My personal experience is limited to two positive cases and a third doubtful one certainly an insufficient number to entitle me to discuss authoritatively the many moot problems, where others with a wealth of material have failed and yet even with this limited material, I have gained certain well founded impressions which I consider worthy of record.

The most prolific contributors to the subject of insolation have been the military and naval surgeons of the United States, Great Britain and Germany. All of these, as well as the civilian recorders of certain large epidemics in New York, Philadelphia, and Boston appear to be agreed that there exist various forms of insolation. All writers differentiate clinically at least two forms, namely sun or heat-stroke and heat prostration. A few authors describe also a third form, "heat exhaustion" so called.

As near as I can gather from the observations of the best authorities sunstroke is characterized by the following more important attributes, in addition to other less important, or secondary attributes. There is always a history of direct exposure to the sun and of

an abrupt onset, with complete loss of consciousness. The integument is, as a rule, hot and dry and flushed. The body temperature is very high the pulse is full and of high tension. On the other hand in heat prostration these symptoms are either lacking or their exact antithesis is present. Thus we find that there is no history of direct exposure to the sun but on the contrary a history of being confined in a close, poorly ventilated room, and perhaps of exposure to artificial heat. The best examples of this form of insolation occur in stokers on steamers, and may occur even when the outside temperature is far below what is usually termed hot. The onset is gradual and consciousness is usually retained. The skin is not hot, dry and flushed, but on the contrary is cold clammy and pale. The temperature in these cases is variable it may be either normal or subnormal or may even be elevated but in instances of the latter it never attains the height it attains in cases of sunstroke, rarely going over 102° F. The pulse, in contradistinction to the former is weak and thready.

Let us now see how far cases of post-operative insolation correspond to these requirements.

If we except the case of Dr. Cunniffe the case that on the day of the operation rode to the sanitarium in an open automobile, inadequately protected from the rays of the sun all of the cases reported had been sick either at home or in a hospital for a number of days prior to the operation and were therefore at no time exposed directly to the sun. Assuming now that the symptomatology previously discussed is correct, it should follow also that cases of post-operative insolation are not cases of heatstroke but of heat prostration.

Nothing definite can be said regarding the rate of onset of the disease because all cases of post-operative insolation were operated upon in general anesthesia therefore the rapidity of the onset, or the lack of it cannot be estimated at its true value. By the time the patient has fully reacted from the anesthesia, the disease may already be far advanced, or it may have just begun.

In most of the cases in which the integu-

ment is mentioned at all we find it stated that the skin of the patient was very hot and dry in one or two a peculiar cyanosis is mentioned. This therefore would be a symptom which is certainly more characteristic of heatstroke than of heat prostration.

I fear that not much reliance can be placed upon the quality character or rate of the pulse. Soon after an anesthesia with its complicating nausea and vomiting the rate and character of the pulse is apt to vary to such an extent, as to detract from its value as a differentiating guide.

In all of the reported cases however we find it emphasized that the body temperature was extraordinarily high we thus find recorded the following temperatures 109 108.2 108.2 108° 107 106.8° 105 and 104 as a matter of fact it might be said that it is practically only upon the presence of these excessively high temperatures and even in the absence of any or all symptoms, that the diagnosis of post operative insolation has usually been made. The registration of the temperature by a thermometer is so exact and so absolutely uninfluenced by the personal equation of the observer that we must look upon it as absolutely reliable in every respect. Judging from the high temperature alone it would follow that all of the cases hitherto observed or recorded belong in the group of heatstroke and not heat prostration.

Almost involuntarily however there arises the question as to whether the above conclusion that all cases of post operative insolation are cases of heatstroke and not of heat prostration and it is a justifiable one. Let me for the sake of argument mention the following hypothetical case. A patient is operated upon let us say for an acute gangrenous appendicitis with abscess six hours after operation the temperature may be either normal subnormal or slightly elevated the skin is cold clammy and pale the pulse is weak and thready and finally let us assume that this operation took place on a hot July or August day. Upon the following day the condition either persists or it is already improved. Ultimately the case recovers without any sequelæ or the case dies within the

first forty-eight hours. There is not a surgeon who has not seen such cases. No one ever thinks of making any other diagnosis than that of mild post-operative shock or ordinary rather severe post-operative reaction and yet are not the hypothetical symptoms just enumerated and the history and course characteristic of so-called heat prostration? I wonder how frequently these cases are overlooked is it not probable that this is the most frequent form of post operative insolation more particularly as it is the form which is more likely to occur in the absence of direct exposure to the sun?

It is not at all remarkable that the few cases of post operative insolation have been recorded in two cities only namely Boston and New York. As I believe these two cities with the addition of Philadelphia record also the greatest number of endemic or epidemic heat prostrations. I do not suppose that there is anything in the geographical location of these cities to account for the greater frequency as even the larger cities further south with presumably higher temperatures fail to report as many cases in proportion. It is perhaps possible to account for the greater frequency of heatstroke in these three cities by the fact that they are more compactly built up and that it is in these cities only that many of the inhabitants live crowded together in tenements.

Trivial as it may appear I believe a second important reason for the greater frequency of heat prostration in these cities is to be looked for in the fact that their population has not as yet learned to dress properly during the summer. I believe in fact I know that most of the people wear too much too heavy too dark and too woolly clothing and I am also convinced that all of these are conducive to the production of heat insolation.

I also believe that the suggestions just made have an important bearing on the question of the production of post-operative heatstroke. The real hot days of the year are in the very smallest minority in New York City the great majority of the days of the year are either cold or verge at least upon coolness. On this account surgeons have learned to fear so much the occurrence of

post-operative pneumonia that they try to avoid it by instructing their nursing staff to be sure to cover the patient well in the operating room upon the transport to and from the operating room and upon the arrival in bed. This has become a sort of fetish and an inviolable rule. I have not the slightest doubt that this needless superheating of the patient is conducive in a great measure, to the occurrence of post-operative insolation.

It was my intention to fortify my standpoint regarding post-operative heatstroke by quoting the unusually high temperatures of New York City on those particular dates. In this however I was doomed to disappointment. I consulted the files of the *New York Sun* upon the four dates upon which cases of post-operative insolation are known to have occurred and was rather surprised to find that with the exception of September 10 1915 on which a temperature of 90° F was recorded the temperature on the other dates was considerably below that namely 83° F June 1 1900 89° F Aug 7 1900 and 83° F July 4 1912. A little reflection soon convinced me of my error. It was well known to me that the deleterious effects of the heat are due not so much to the excessive height of the temperature on a particular date but more to a long continued term of fairly high temperature with a very high percentage of humidity and absence of any breeze in other words what is commonly called a heat wave. The longer the atmospheric conditions just described exist, the greater will be the number of heat prostrations. When I again consulted the files of the daily press upon the dates mentioned from this viewpoint, I found just the conditions described and also that they had been in existence for some time preceding that date.

TREATMENT

Whenever the atmospheric conditions are favorable for the production of insolation, all operating room activities should cease with the exception of those of an urgent nature. It is quite within the range of possibility that insolation may occur even in a non-operated individual but the exhaustion dependent upon the operation is lacking and may be just

the factor which determines the occurrence of insolation and the success or failure of treatment instituted.

In all cases operated upon during a wave, the greatest regard should be had to the comfort of the patient. As already indicated all the needless swathing in blankets and hot water bottles is to be prohibited. On the contrary at such times coolness the lightest of covers are indicated. Morphine is also in order and desirable. Cool drinks should be permitted much earlier than is generally the custom after operations.

It has already been pointed out that not far only that particular form of insolation which is characterized by very high temperatures and which is called heatstroke has been recognized as a post-operative complication. This is perhaps due to a lack of our diagnostic acumen as it is quite possible that the second variety or heat prostration so called, is the more frequent. While the etiological factor appears to be identical in both, they differ widely in their symptomatology and what is of the greatest importance also in the therapy.

In heatstroke the temperature is so high that every effort should be made to reduce it and to nullify its deleterious effects. Unfortunately we cannot avail ourselves in the cases of the antipyretic properties of coal tar products on account of their depressing effect upon the heart. Recourse must be had therefore to physical measures to reduce the temperatures. The best of these is hydrotherapy properly executed and carried out in the form of sponge baths with water. An ice cap applied to the head is not only grateful to the patient, but materially aids in reducing the temperature and combating the delirium of the patient. Enemata or Murphy infusions with ice water coming into contact with a large volume of the superheated blood should also be tried and will also be followed by success. The form of treatment would, on the other hand, be entirely contra indicated in that variety of insolation which we call heat prostration. In this form the temperature is not only not elevated, but in many cases is even subnormal. The exact opposite form of treatment

therefore indicated namely the patient should be well covered and surrounded by hot water bottles subcutaneous or intravenous saline infusions, or warm rectal infusions are indicated.

The rate and quality of the pulse is to be controlled and forms a valuable guide as to the character and amount of stimulation called for

In a certain number of cases of insolation

there has been found a peculiar degeneration of the blood which manifests itself by a laking This suggests the possibility of venesection and blood transfusion provided a suitable donor can be found at short notice

PERFORATION IN TYPHOID FEVER

WITH REPORT OF A CASE ASSOCIATED WITH ACUTE TYPHOID APPENDICITIS IN A CHILD
AGED 7 RECOVERY¹

By IRVING H. EDDY, M.D., CHICAGO

Instructor in Gynecology, College of Medicine, University of Illinois

IN discussing this most important topic of surgery one cannot refrain from praising the courage of the early workers in this field. In 1884 von Leyden first proposed to treat the resulting peritonitis of typhoid fever through operative measures and at that time said

I cannot longer forbear mentioning something I have for a long time had in mind namely whether or not it is possible to treat peritonitis by operative measures. The idea is rational enough when one considers that suppurative peritonitis is very similar to suppurative pleuritis

Further he says

But I must leave it to the surgeons to determine whether it is possible to accomplish anything by operation in this condition, but one thing is certain, it seems to me that herein lies a most fruitful field for investigation.

During the same year appeared an article by the renowned Mikulicz in which he reported three cases of peritonitis treated surgically and there is little doubt that one of them was a perforated typhoid ulcer. While there is some doubt as to the authenticity of this case there is no doubt that Mikulicz's great teaching encouraged the surgical treatment of peritonitis

Lucke and Kussmaul however seem to receive the credit of being the first to have

operated on and reported an authenticated case of perforation. During the same year Bontecou reported a case. To Professor J. C. Wilson in 1886 is given the credit of being the first writer on the subject in the English literature and at that time he made the following statement

Granted that the chances of a successful issue are against you that the lesion of the gut may be very extensive that the vital forces are at a low ebb nevertheless the courage to perform it will come of the knowledge that the only alternative is the patient's death

As early as 1762 A. G. Richter of Vienna suggested the advisability of draining the peritoneal cavity for suppurative peritonitis. Among early writers on the subject especially are to be mentioned Keen, Cushing, Finney, Van Hook and others. In 1898 Keen published his extensive monograph Surgical Complications and Sequels of Typhoid Fever in which he reported a collection of 83 cases from the literature and in 1899 collected 75 additional cases making a total of 158 cases operated on with a mortality of 76.59 per cent the mortality of non-operative cases being quoted by Murchison as 95 per cent. At this time Keen made the following statement

The earlier the moment at which the operation can be done after the immediate shock of the perforation (provided, of course, there has been any as is sometimes not the case) the better it will be for the patient, every hour thereafter counts, since the infection of the peritoneum becomes more diffuse and intense.

In discussing the above, Cushing made the following reply

It is hard to understand Dr Keen's advocating delay until symptoms of shock have passed away and his preference of the second twelve hours for operating when one speculates that extravasation perhaps of virulent organisms is with all probability continuously taking place while we are waiting.

In Keen's statistics in which the time was given before operation the results were as follows

	No. of Cases	Died	Recovered
Operated on during first hours	36	29	7
Operated on during second hours	39	7	
Operated on after 24 hours	83	65	8

FREQUENCY OF PERFORATION FOUND AT AUTOPSY

The frequency of perforation varies greatly as is shown by the following statistics of various epidemics

In a series of 105 autopsies at Johns Hopkins Hospital perforation was found in 30 cases and occurred more frequently in ulcers with adherent sloughs. In Munich, in a series of 2 000 autopsies, perforation occurred in 57 per cent.

Author	Autopsies	Percentage
Murchison, 1st series	455	5.8
Cunhaumann	575	6
Heschel, Brouardel, Thoblot	667	7
Mackenzie	737	35.7
Murchison, 2d series	65	
Heschel, 1840-1849	27	4.4
Brouardel and Thoblot†	7	3
Griesinger	8	8
Oster	6,849	

Various London hospitals
†From English, French and German sources

The United States census reports of 1900 give the total deaths from typhoid fever as 35 379. As 12 per cent of the total death rate is shown to be due to perforation there died during that year in the United States 4,222 from perforation of the bowel.

FREQUENCY OF PERFORATION AS TO NUMBER OF CASES TREATED

	No. of Cases	Per centage
In Leipzig	1636	
In Hamburg	4004	6
Griesinger	600	3
Johns Hopkins Hospital	839	7
Murchison	580	3
McCrae, Montreal	77	6
Mackenzie, London	973	3.6
Hare and Bribbane	373	9
London and French Hospitals	2350	3.4
Scott, Philadelphia	3006	6

Total average—more than 3 per cent.

*Three recovered by operation

LOCATION OF PERFORATION

Author	Ileum	Colon	Appendix	Mitchell's diverticulum	Jejunum	Cecum	Rectum	Misc. O.
Including Oster's with those of Lambermester								
Mackenzie, and Fitz	506	56	3	4	4			
Cunhaumann, 64 cases	5							
Scott 30 cases	43		4					
Hawkins 7 cases	6	5	3			3		
Total	66	73	40	4	4	3		

The location of perforation relatively coincides with the studies of Baer as to the location of ulceration which is as follows

Item	No. of Cases	Per Cent
Ileum	13	89
Cecum	396	30.3
Jejunum	358	5.9
Ileocecal valve	89	6.7
Ascending colon	6	3
Transverse colon	6	4.5
Descending colon	6	6

TIME OF PERFORATION

Finney analyzed 112 cases with 66 perforations occurring as follows

20 during the second week.
36 during the third week.
9 during the fourth week.
The shortest period was four days.

In 193 cases Fitz found that perforation occurred in 88 cases during the second and third weeks, while 90 per cent of the remainder occurred during the fourth fifth, and sixth weeks.

Author	AGE					
	Less than 15	15-20	20-30	30-40	40-50	50-60
Finney	15	1	10-15	35	5	
Osler	8	3	0	15	0	6
Fitz		46		4		4

In Finney's series the youngest was 6 years. In Scott's series of 153 cases, only 5 were less than 15 years of age, the youngest being 8 years.

According to Curschmann, Topin, Rilliet, Rocher and Henoch, children under ten years of age are less prone to perforation, and that pathological study shows that the medullary swelling of Peyer patches and the solitary follicles is not so great as in adults, diarrhoea not so common and loughing not so marked, which undoubtedly explains the low percent age of perforation. This statement however is disputed by Jopson, who collected 45 cases of age being given in 44 as follows:

Age	Cases	Age	Cases
5	4		
6	4		
8		3	5
9		4	5
10	6	5	1

Total 44

In 217 cases among children collected by the same author perforation occurred 15 times or in 7 per cent as compared with the previous table in which perforation occurred in more than 3 per cent. Further one may note that only 21 of the 44 cases reported by him were under 10 years of age. The fact that only 1 case under 10 years of age could be found in the literature to 1909, the time of his article, proves in itself the infrequency in children. Griffith and Ostheimer in 302 cases under 15 years of age found perforation in 1 case, the youngest found in the literature.

SEX

In 444 cases Fitz reports 11 per cent in males and 9 per cent in females.

MORTALITY

Of 16 cases operated on at the Johns Hopkins Hospital between 1890 and 1900 6 recovered.

Keen's reports show 158 cases operated on with a mortality of 63.9 per cent.

In Jopson's series the type of disease was given in 51 cases as follows: mild 8, moderate 11 and severe 9. Of the mild recovered 3, died of the moderate 5 recovered, died of the severe 10, died 10— a mortality of a little more than 50 per cent.

Scott's report from the Pennsylvania Hospital were as follows:

	Age	Sex	Perforation	Recovery	Mortality
Males	11	5	4	3	3
Females	11	3	4	4	4
Total	22	8	8	7	1

Of the 11 cases reported by Scott recovered 7, the mortality being 36 per cent.

ETIOLOGY

Of the etiology that favours perforation we know comparatively little, however when one examines the bowel with ulceration almost to the peritoneum we wonder not that perforation occurs but rather at its infrequency. In children the lesions are not so marked as in adults, and especially in this true at the depth of the ulcer. Unquestionably this explains the infrequency of perforation in children.

Violent muscular movement and distention of the bowel may increase the danger of perforation. Perforation is more likely to occur in cases with diarrhoea as shown from the statistics of John Hopkins Hospital. Of 50 cases of perforation 30 had diarrhoea 16 at the time of perforation. This point becomes more forcible however when it is known that of 59 cases only 19 per cent had diarrhoea during the course of the disease. The time of the perforation coincides with the intensification of the lough and is demonstrated by the large percentage of cases occurring at the end of the second and during the third week.

Mechanical factors as meteorism especially if of sudden formation, solid contents forced movements as vomiting, dietary error causing increased peristalsis are important.

Perforation is more likely to occur between the ages of 18 and 40 while after 40 it is relatively infrequent.

SHEPPARD'S CASES

Case	Pain	Pulse Rate	Temperature	Leucocyte Count	Blood Pressure	Peristalsis	Vomiting	Collapse
1	Slight	80 to 170 4 1/2 hours, followed by fall 30	100. 1 104 in 3 hours later fall	5945 after 30 hours	88 to 5 hours Fall to 90	Slight	N	N
	Yes	80 to 50 3 hours	100 to 3 hours	3600 to 1 000 in 3 hours	94 1 in 3 hours	Decided	N	Yes
3	Slight	94 No change	1 104 in 7 hours, Fall 98.5 1 hours	8800 maximum	80 no change	Late	Yes	N
4	Yes	88 to 60 Running	98 97	Previous 600	Impossible to estimate	Yes	No	Extreme
5	Slight	61 50 hours	1 change	4500 maximum	93 no change	Slight	N	Late

Perforation is more frequent in men than women, which is explained perhaps partly by man's mode of living, the late observation of many cases and their impatience during convalescence.

The fact must be borne in mind that perforation may take place at any period of the disease and every patient should be carefully guarded.

SYMPTOMS

This grave complication occurs suddenly and very frequently unexpectedly; however it may be preceded by increased abdominal distention, colicky pain, borborygmus, diarrhoea, or hæmorrhage may be the warning sign. Six cases of hæmorrhage preceded 30 cases of perforation at Johns Hopkins Hospital.

At the time of perforation the patient (if mentally alert) is seized with a severe pain of rapid progressing intensity greatly increased by respiration passive or active motion and usually on palpation the greatest point of tenderness will be found in the region of the ileocaecal valve.

Pain in typhoid fever was studied by McCrea in 500 cases at Johns Hopkins Hospital. He found that about 40 per cent of the cases are free from both pain and tenderness and rather less than 20 per cent have tenderness. It was most constantly present with perforation usually sudden in onset severe in character and paroxysmal in occurrence.

Associated with pain are retching and vomiting the abdomen becomes progressively distended the walls become smooth and glistening respiration thoracic, and the paresis of the muscular layer of the intestine attains a high degree. The vomiting may become fecal in character and even suggest obstruction or ileus. The features assume a hypocratic expression the nose pinched the extremities cold and the face and body covered with a cold clammy perspiration. The pulse increases in rate becomes quite compressible and oftentimes thready.

The blood pressure was carefully studied by Crile and Sheppard. Crile found the highest systolic pressure in uncomplicated cases and with normal arteries as measured by a Riva Rocci sphygmomanometer in 115 cases of typhoid fever 138 mm. and the lowest 74 mm. The mean during the first week was 115 second week 106 third week 102 fourth week 96 and the fifth week 98 mm. The mean pressure of all the typhoid was 104 mm. In 20 cases of acute peritonitis recorded by the same observer with the same instrument and otherwise similar cases the highest was 208 mm. and the lowest 156 the mean 166 mm.

In 5 cases diagnosed as typhoid perforation in which pressure determinations were made (4 of these verified by operation or autopsy one case not operated on) the pressure rose from 116 to 190 mm. during a period

of four hours. The second case a lad of 12 years admitted with general peritonitis pressure 105. Vidal positive immediate operation later abdominal symptoms of peritonitis disappeared and the pressure fell to 80 mm. On the eighth day infection passed through the wall and peritonitis developed the pressure again rising promptly from 84 to 110. In the third case a slow perforation the pressure rose from 116 to 165 in two hours. The fourth case a physician entered the hospital with general peritonitis and blood pressure 165. No operation was performed. Autopsy disclosed perforation. Previous pressure unknown. A fifth case typhoid had pressure of 208. At operation perforation and diffuse peritonitis were found.

Sheppard's observation of 41 cases of typhoid fever near and during the fourth week, showed an average of 98 mm. The cases tabulated above, showing the various symptoms were reported by him and from them he deduced the following conclusions.

The pulse rate rises in almost all cases.

The blood pressure rises in most cases but may be difficult to obtain owing to extreme restlessness. Hemorrhage occurring simultaneously may greatly alter the blood pressure. Signs are most marked two hours after perforation and the blood pressure falls to the original level as rapidly as it rises. Sheppard also made blood pressure observations in the presence of distention pain increased leucocytosis and pulse rate and found no change except in one case of bronchitis. His final deduction is that a sudden rise in blood pressure is positive evidence of perforation while an unchanged pressure is not of negative value.

In the majority of cases there is an immediate elevation of temperature which in a very few hours is followed by a rapid fall. Rigidity and muscular spasms are not usually present to a marked degree immediately after rupture. Chills are rather a common symptom and is often followed by a cold perspiration. Leucocytosis is a very important symptom but to be of the highest value the blood picture must be studied frequently during the course of the disease.

Considerable importance has been given to

the disappearance of liver dulness as a symptom of perforation by some writers while others discredit it by stating it to be comparatively rare.

The Vidal reaction should be taken repeatedly in all suspicious cases of typhoid and will be of the utmost value if previously positive in a suspected case of perforation.

Hiccough if present is an important symptom because of its infrequency during the normal course of the disease and every patient should be examined also for the presence of the free fluid in abdominal cavity as a variable quantity may be present from the escape of liquid contents.

DIAGNOSIS

In arriving at a diagnosis a definite distinction should be made between the symptoms of immediate perforation and those due to the peritonitis resulting therefrom. Unless this all important distinction is thoroughly recognized we have deprived our patient of his chances of recovery. The attending physician must ever be on the alert in every case or suspicious case of typhoid to accomplish this distinction and the nurse or house physician in charge should be instructed to notify him immediately of any change in the symptomatology or condition of the patient. To be able to arrive at the proper conclusion one must especially have a clear clinical picture of the following conditions before him: acute appendicitis, hemorrhage, ileus, acute intestinal obstruction, acute pelvic infections, acute cholecystitis or cholelithiasis.

The diagnosis of acute appendicitis in most cases is comparatively easy. Too much stress cannot be emphasized in taking the history of every case offering difficulty in diagnosis when properly elicited if the patient be of moderate intelligence much valuable information can be obtained that will assist us in arriving at a proper conclusion. The pain of appendicitis not infrequently beginning in the epigastrium radiating over the entire abdomen greatly relieved for a time after the stomach has been emptied of its contents by vomiting followed by localized tenderness and rigidity over Burney's point.

absence of a Widal and with comparatively little disturbance of the pulse and temperature curve minus shock, will rule out appendicitis.

Of 717 cases treated at the Montreal General Hospital hæmorrhage occurred in 10 per cent. In hæmorrhage if severe, the pulse becomes rapid and compressible the blood pressure falls, the skin acquires a waxy pallor there is lividity and coldness of the limbs, the temperature is subnormal, and little or no pain. This presents a clinical picture that cannot be misconstrued.

In ileus or intestinal obstruction we not infrequently have a history of an inflammatory condition the presence of possibly strangulated hernia, or of a previous operation.

The first symptom to appear is a severe gripping pain more or less localized paroxysmal in character. The peristaltic wave can frequently be seen ending abruptly and, if obstruction is incomplete flatus and status may be forced through with a gurgling sound or if complete, obstinate constipation nausea, and vomiting are early and distressing symptoms. At first the normal stomach contents are ejected but soon this is followed by bile, dark fluids and later intestinal contents with fecal odor. The abdomen at first flaccid, soon becomes tympanitic the pulse increases rapidly becomes more or less thready the temperature may be subnormal and the patient presents the general picture of collapse however the symptoms as a whole develop less rapidly than do those of perforation.

The pain of pelvic lesions is usually more continuous, but not so severe except, perhaps, that of extra uterine pregnancy. Vomiting is not frequent in these conditions. The not infrequent bilateral condition, the tenderness and rigidity obtained by double palpation, the presence oftentimes of a mass in the pelvis associated with tenderness and rigidity of the vaginal vault, will easily rule out pelvic lesions of an inflammatory character while if we suspect extra uterine pregnancy the early signs of pregnancy collapse, associated with subnormal temperature absence of leucocytosis, the presence of uterine hæmorrhage and a fluctuating mass in the tubo-ovarian region will be valuable aids.

The not uncommon association of gall bladder infections and typhoid fever calls for special consideration. A study of the literature shows that perforation is rather infrequent after 40 years of age while on the other hand gall bladder infections are relatively infrequent before. It is more common in females than males and especially in those who have borne children. The attack is frequently associated with indiscretion in diet, coming on suddenly with severe paroxysmal pain in the epigastrium and right hypochondric regions. Repeated vomiting is the rule and the contents are usually richly bile stained. The abdomen is distended and rigid but the greatest point of tenderness is usually at the costal margin. The temperature rises while the pulse is comparatively slow which is an extremely important diagnostic point. A study of the literature demonstrates that perforation of the gall bladder in typhoid fever does occur and issues a warning sign to be on our guard.

Finally if our cases are studied carefully and the conditions that are likely to cause confusion kept closely in mind, few mistakes will be made, and many lives saved.

TREATMENT

There is only one method of treatment in these cases requiring discussion which was well stated by Mikulicz in 1884, when he said:

If suspicious of perforation one should not wait for an exact diagnosis and for peritonitis to reach a profound degree, but, on the contrary one should immediately proceed to an exploratory operation which in any case is free from danger. How much more true the above statement is in present day surgery is well understood. Our patient's life depends on the recognition of the perforation, and not the resulting peritonitis, and unless we are capable of doing this we are a stumbling block to the patient's welfare.

As soon as perforation is recognized or greatly suspected the patient should be given morphine immediately. Quoting Morris:

We are choosing the lesser of two evils, for the tremendous shock is more deadly than are the escaping bacteria when the patient is not quieted by opium.

Temperature chart. Case C. H. Note sudden rise of pulse and temperature on the 18th at time of perforation.

There seems to be a difference of opinion as to the choice of anaesthesia. Woolsey believes these cases take gas and ether well. In two cases reported by him cocaine was used satisfactorily for exploration but retraction of the edges and the necessary handling of the inflamed bowel were painful and this together with the realization of being subjected to an operation cause more shock than general anaesthesia.

As to choice of incision most surgeons will agree on the right rectus or McBurney's as statistics conclusively show that more than 80 per cent of the cases perforate in the lower eighteen inches of the ileum and the nearer we are to the lateral wall, the less the danger of spreading the infection over the peritoneal cavity. The perforation should be located as quickly as possible and with little handling of the bowel.

The perforation can be closed in most cases with a purse string reinforced with a row of Lambert or mattress sutures the greatest care being taken however not to constrict the lumen of the bowel which if done will almost certainly result in ileus. In all cases the ileum should be explored as far as the inflammatory process extends for multiple perforations or deep ulcers. Some cases may require resection where the perforation is large but unfortunately the quickly resulting peritonitis and extreme shock of such an extensive procedure has proved fatal in nearly all reported cases of this character.

The peritoneal cavity should be carefully sponged with saline solution but irrigation should be avoided unless a general peritonitis exists. Thorough drainage should be employed and the Fowler position obtained as soon as the patient's condition will permit.

Intravenous subcutaneous or proctoclysis should be used according to the demand of the condition of the patient. Morphine should be continued until the peritonitis becomes well localized and the bowel not disturbed in any way. Later they should be taken care of by flushing and small doses of opium. No food whatever should be given by mouth and if vomiting has been quite severe lavage should be used before the patient comes from under the anaesthetic. Stimulation should be used according to the demands of the patient and the condition of the heart muscle carefully observed.

In conjunction with this paper I wish to present the following case:

C. H. age 7 Previous history Child showed some malnutrition during first year but rapidly outgrew it. Had measles about two years ago and a few months later chicken pox and mumps, all of which were mild in character and left no sequelae otherwise has been exceptionally well.

Present illness On August 28, 1914, after returning from a ride, he complained of headache, and the next few days seemed to have a cold which did not yield to the usual home remedies. He appeared languid and drowsy. Dr. J. M. Nicholson was called to see him September 9 and after a careful examination a diagnosis of bowel infection was made. The bowel movements were rather watery.

and decidedly green in color. The patient had a variation of temperature from 98° to 101.5°. The following day the temperature varied from 98° to 103 and on the 11th 98.4 to 105° with continuation of the green movements.

No improvement was shown during the next few days and I was called in consultation the evening of the 15th. A careful examination was negative other than abdominal trouble. Much distention was present but no special tenderness, and the bowel movements were decidedly green. Until this time the child had been cared for by the mother. A nurse was put in charge of the patient and a Widal suggested if improvement did not occur immediately.

On the 6th there was little change. The 17th, at 10:30 a.m. temperature 99.5° pulse 60 respiration 28 at 3:30 p.m., temperature 101 pulse 120, respiration 28 and at 6 p.m. temperature 102.5° pulse 120 respiration 28. All movements of the day were recorded as very green and the result of normal saline flushings. 7:30 p.m. the child had a severe chill lasting 10 minutes which was followed by a very severe pain in the right side. The pulse became weak and the lips and fingers cyanotic. The grave condition of the patient was recognized immediately by the nurse and Dr. Nicholson was called. An immediate blood examination was made by Dr. Nicholson showing a leucocytosis of 33,000, and the patient was ordered to St. Joseph's Hospital. The temperature at 8:5 p.m. was 103.6° pulse 160 respiration 40 at 9:00 p.m. temperature 105° pulse 160, respiration 40 at 9:45 p.m., temperature 105.4° pulse 140 respiration 40. The patient entered the operating room at 1:30 p.m. with the typical expression of collapse and peritonitis. I was assisted by Dr. Nicholson, to whom I wish to give due credit for his alertness. A McBurney incision was made and the following conditions discovered:

1. A very severe appendicitis appendectomy
2. A perforation about 16 inches from the ileocecal valve which was rapidly closed and two other ulcers that showed clearly through the peritoneal coat were reinforced. The abdominal cavity was carefully sponged with normal saline solution and a small median incision was made for counter drainage. The patient was returned to his room at 1:30 a.m.

At 1:30 a.m. pulse 160, respiration 40. Stimulants and morphine were given. At 7:00 a.m. axilla temperature 100 pulse 140, respiration 32 at 9:00 a.m. temperature 100° pulse 120—stronger respiration 34. Digitalin 1/200 was given every 4 hours. 6:00 p.m. temperature 100 pulse 140 respiration, 8:100 m. temperature 99.6°, pulse, 90 respiration, 28—but very restless. September 9 temperature varied 99 to 101 pulse, 90 to 136 very weak. September 10, temperature varied 100 to 104.6°, pulse 128 to 52. Abdomen greatly distended with marked intestinal peristalsis.

Eserine gr 1/200 given at 9 p.m. and 3 a.m. with calomel gr 1/30 every hour. 7:00 a.m. watery bowel

movement and much gas. September 11 temperature 100 to 101 pulse 128 to 136 respiration 24 to 28. Eserine 4/10 and 4 involuntary bowel movement 1:30 p.m. and semicolid bowel movement at 8:30 p.m. Positive Widal obtained. September 12 temperature 100 to 102 pulse 108 to 128 respiration 20 to 24. Fairly good night. Eserine at 8:1 and 8 September 13 temperature 99.6 to 103.4 pulse, 100 to 135 September 14 temperature 99.8 to 103.6° pulse 104 to 128 Sept. 15 temperature 100. to 102.6° pulse 120 to 128 September 16 temperature 99.4 to 103 pulse 112 to 8 September 17 temperature 98.6 to 100° pulse 100 to 118 September 18, temperature 98 to 98.6 pulse 65—1 September 19 and 20, temperature 97 to 98.6° pulse 96 to 98 October temperature rectal 96 to 97 pulse 80 to 90, very irregular acute myocarditis present. October 3 rectal temperature 96.4 to 97.4 pulse 65 to 88 very irregular. Patient cold external heat applied. Pulse remained very irregular during the next week after which time recovery was uneventful.

In conclusion the following deductions may be drawn

1. While perforation varies greatly in different epidemics, about 1 per cent of the total death rate is due to this complication.
2. That perforation occurs in about 3 per cent of all cases treated.
3. That perforation is relatively infrequent in children.
4. Statistics show that over 80 per cent of the total perforations occur in the lower ileum.
5. That the location of perforation coincides with the study of Baer.
6. That the majority of cases perforate during the second and third week.
7. Diarrhoea is an important factor in its production.
8. Acute abdominal pain during the course of typhoid should always be taken seriously.
9. The sudden rise of blood pressure is positive evidence of perforation while an unchanged pressure is not of negative value.
10. The importance of a careful study of the blood cannot be overestimated.
11. The welfare of the patient depends on our ability to differentiate between the symptoms of perforation and those of the resulting peritonitis.
12. The treatment of perforation is surgical and the death-rate is in inverse ratio to the length of time allowed to elapse before operation.
13. Operations are indicated as soon as perforation has taken place and should be continued until the peritonitis has become well localized.

DELIVERY BY ABDOMINAL SECTION¹

By EDWARD P. DAVIS, M.D., F.A.C.S., PHILADELPHIA

NOTHING has been more striking in the evolution of medical science than the advance which has taken place in a comparatively brief time in obstetric surgery. The establishment of cesarean section upon a basis of success comparable with that of other abdominal operations was a great advance over the uncertain and unsatisfactory and difficult deliveries by forceps or craniotomy. But recently it was found that in addition to the problem of delivering the child safely a very considerable range of pathological conditions accompanying pregnancy may be successfully dealt with at the time of delivery. The fact that it is difficult and often impossible to positively know the condition of pelvic and abdominal organs without section and that during labor serious changes may occur in intra-abdominal conditions which may result in infection or hemorrhage has made delivery by abdominal section in many instances a far more complicated procedure than simple cesarean section.

Highly contracted pelvis has been made one of the simplest complications of parturition by the success of a classic cesarean section, but pathological conditions in the pelvis and abdomen complicating pregnancy may be of several varieties.

The most serious accident in labor or in pregnancy is rupture of the uterus and whether this occurs during parturition or during pregnancy the most successful treatment is by abdominal section. Rarely is it possible to save the uterus. Hysterectomy in the great majority of cases is indicated and if it is thought wise to drain through the vagina, extirpation of the uterus may be chosen.

Foci of infection in pelvic or abdominal organs developing during pregnancy may threaten the patient's life through the bursting of an abscess and the escape of its contents into the peritoneal cavity. One of the difficulties in diagnosis in such a case is

the fact that such a focus may remain quiescent during the greater part of pregnancy and its existence only become apparent through some accident. In the experience of the writer a woman of unknown antecedents passed easily through a spontaneous labor and a puerperal period of two weeks without evident complications. During the third week while convalescent and acting as helper in a ward after lifting a bucket of coal she complained of vague indefinite abdominal pain. Influenza was epidemic at the time and many of her symptoms were those of influenza. Peritonitis rapidly developed and section undertaken too late revealed an old focus of infection in a tubal abscess which had ruptured upon exertion causing fatal infection. Could the existence of this abscess have been known at the beginning of labor and abdominal section promptly performed the patient's life might have been saved. It would have been wiser in that case to have delivered the child by section without labor and then dealt with the abscess.

A not uncommon and very great risk to the parturient woman is appendicitis. If this condition is not met promptly by operation and abscess forms the uterus will usually undergo contraction and abortion or labor develop. In either event, the contractions of the uterus will rupture the wall of the appendiceal abscess and infection will follow. The majority of obstetricians remove the diseased appendix at whatever period of pregnancy appendicitis may develop and with excellent results. Should appendiceal abscess complicate gestation and viability it would be safer to open the abdomen empty and close the uterus and then deal with the appendiceal condition.

Obstetricians have learned by experience that it is dangerous for a woman having a septic focus in pelvis or abdomen to undergo the disturbance of labor and there is no method combining prompt delivery and efficient

treatment of the septic condition present which compares with abdominal section.

The presence of pelvic or abdominal tumors complicating pregnancy is also an indication for section. Ovarian tumors during pregnancy have an especial tendency to twisting of the pedicle and the gangrenous changes in the tumor which follow this accident. Fibroid tumors which block the pelvis or seriously interfere with the contraction of the uterine muscle furnish a valid indication for section. Multiple fibroids of the uterine muscle which may produce no tumor large enough to be detected by palpation prevent the physiological development of labor and are best dealt with by delivery by section. Cancer of the cervix calls for the prompt extirpation of the uterus so soon as discovered, but if the patient be near viability and wishes to take the risk of the prolongation of pregnancy to secure a living child delay may be practiced in accordance with the patient's request.

The topic receiving most attention at present from obstetricians throughout the principal clinics in this country and abroad is the treatment of advanced pregnancy complicated by premature separation of the placenta, whether normally situated or placenta prævia. This topic was discussed at several international meetings just before the European War and in the literature of the year 1915 the number of papers upon this subject far exceeds those written upon any other topic. Obstetricians recognize fully the fact that many of these cases must be dealt with by the general practitioner in emergency. Certain well-defined procedures are available under these circumstances. But as hospital facilities are becoming more abundant in this country and means of transportation more efficient, more of these cases will receive hospital care. Under these circumstances, there can be no question but that premature separation of the normally implanted placenta is dealt with most promptly and safely by section.

Obstetric opinion may be divided as to the choice between vaginal and abdominal section, but the writer's preference is decidedly for the latter. There is a much wider dif-

ference of opinion concerning the treatment of placenta prævia by abdominal section. Many obstetricians limit the operation to those cases where the cervix is undilated and not readily dilatable and where mother and child are in good condition, the child's heart sounds being sufficiently strong to indicate that it has not suffered greatly from the loss of maternal blood.

In the mind of the writer placenta prævia is analogous with ectopic gestation. By ectopic gestation as commonly understood, we mean the attachment of the ovum outside the cavity of the uterus, and the common acceptance of this term limits this attachment to the wall of the uterus and the contents of the pelvis or abdomen. Under these circumstances, the danger of infection aside from that which accompanies an operation is very little and arises from the proximity of the ectopic gestation to the intestine and its contents of feces and bacteria. The great risk of ectopic gestation is ordinarily hemorrhage.

When placenta prævia is considered the ovum at all stages of pregnancy is attached very near the vagina, which invariably contains bacteria. Dilatation of the cervix to some slight extent is inevitable and this is at once accompanied by the danger of infection. This danger is now appreciated and the majority of obstetricians have abandoned in placenta prævia tamponing the vagina or other forms of treatment through the vagina, except such as have for their object the emptying of the uterus by the removal of its contents. In placenta prævia the lower portion of the uterus is unusually rich in blood and the separation of the placenta opens many channels for infection. Post partum hemorrhage is a frequent accompaniment of vaginal delivery in placenta prævia.

Under these circumstances, in cases where the greater portion of the cervix is covered by placenta and the membranes are not readily available for rupture, it is the writer's belief that delivery by abdominal section is indicated.

Modern surgery has reiterated anew the doctrine of the importance of shock. In all

departments of surgery the effort is constantly made to improve anæsthesia and to block those channels by which dangerous reflexes may be conveyed to vital centers. Obstetricians recognize the fact that there are patients in whom the physiological phenomena of spontaneous parturition cannot be successfully carried out and in whom the occurrence of uterine contraction and dilatation end in failure to deliver the child and in dangerous depression. The phrase physiological incompetence for labor has been proposed by some who have written upon this subject. Under these conditions anæsthesia and delivery by abdominal section at a most favorable time and under the most favorable circumstances give better results than a painful and tedious labor followed by difficult vaginal delivery and its inevitable traumatism.

The present world crisis has considerably increased the value of human life through the enormous waste which war has occasioned. Hence the preservation of infant life is at present a topic of widespread interest. While the ancient rule holds that the mother's interests should first be considered, cases arise in which the mother's interests are not unduly jeopardized if the birth of the child be secured by abdominal delivery. Patients who have lost children in previous labors through disproportion or physiological incompetence although the pelvis may be of average size may rightfully elect delivery by section in the interest of the child. Were the mother only to be considered craniotomy might be employed in the failure of spontaneous labor.

Very rarely conditions arise where prompt delivery under anæsthesia is indicated in the interests of mother and child because some condition of visceral disease threatens the lives of both. In the writer's experience delivery by abdominal section in eclampsia is very rarely indicated and yet occasionally, where the mother has apparently been in good condition before the first convulsion and where the child's heart beats are strong and regular and no sign of labor develops, immediate delivery by section may be admitted. In cases of serious disease of the heart where the child is abundantly viable and compensa-

tion is failing it may be possible to save the life of the child and prolong that of the mother by delivery by section without labor.

Under what conditions shall delivery by abdominal section be terminated with the sterilization of the mother? A plain indication arises where there is abundant evidence that the uterus is the site of an active septic infection at the time of labor. In these cases a cardinal rule of operation calls for the removal of the fallopian tubes and body of the uterus and the leaving of the uterine stump outside the peritoneal cavity or if the operator prefers the extirpation of the entire uterus. The removal of the ovaries or their preservation must depend upon the age of the patient and the condition of the pelvic tissues at the time of operation.

Shall the obstetrician act as judge in those unfortunate women who are habitually immoral, diseased and mentally, physically and morally degenerate. And shall the procreative power of such be terminated by operation? In these cases the cardinal rule of the profession is to save life without regard to the moral character of the individual, but in those women who are imbecile, epileptic, insane or degenerate the permission of parent or guardian should be obtained for sterilization. If such is not available consultation should certainly determine the propriety of the step.

Have husband and wife the right to decide that sterilization be performed?

This question may be a difficult one to decide but in the experience of the writer such a request will rarely be made of the obstetrician unless there is the history of previous unsuccessful and dangerous parturition. Such is the success of repeated section that this choice should not be hastily made and if the parents are sound and there is every reason to believe that the offspring are healthy the claims of repeated section must be urged. But if the parents decline to take the risk of repeated section and request sterilization it is a question whether the obstetrician has a right to refuse such a request.

The Roman law which called for immediate section upon the body of a woman pregnant near term and dying suddenly to save the

child still holds, and in the writer's observation three cases have arisen where this procedure was clearly indicated. Caution must be observed not to promise the ultimate survival of the child for in some of these cases the disease which ends the mother's life may render impossible the continued life and growth of the infant. In abdominal or other ectopic pregnancy section is clearly indicated.

By whom shall delivery by abdominal section be performed?

The best results will be obtained when these operations are done in well-equipped maternity hospitals and by obstetricians. Neither the general surgeon nor the gynecologist has sufficient experience in pregnancy and parturition to make him a wise judge in deciding the important questions which these cases present. These patients call for far more than merely technical skill. A thorough knowledge of the pathology of pregnancy and labor not only in the mother but in the fetus, is necessary for an intelligent choice of the variety of operation and the time at which it should be performed. Improvement in obstetric teaching and the development of maternity hospitals are gradually producing competent obstetricians, and such should deal with these cases.

It may not be without interest to allude briefly to the writer's experience. These cases came from an obstetric service in a large city and were operated upon in a small maternity hospital where the facilities of operation while practically adequate, were not those of a luxuriously appointed surgical amphitheatre. These cases cover a period during which obstetric surgery was developing in this country and therefore represent what may fairly be taken as an average.

The indications for operation embraced the field of obstetric pathology outlined in the preceding paragraphs.

The operations consisted of 129 classic cesarean sections 50 hysterectomies 10 which the stump was dropped and the abdomen closed without drainage 32 Porro operations in which the stump was fastened by a clamp

in the lower end of the abdominal incision 3 extirpations of the uterus, and 2 sections performed at the moment of maternal death—a total of 216 operations. These cases may again be divided into those that were in fair condition at the time of delivery with no fatal disease of the viscera and apparently uninfected by sepsis, and those which were at the time of delivery infected or suffering from some fatal disease affecting the important viscera. Of the former cases in good condition, there were 151 with one maternal death—a maternal mortality rate of 0.066. Of those cases that were infected and in bad condition there were 65 with 16 deaths—a mortality rate of 26 plus per cent. the mortality of the entire series being 8 per cent.

The one case of death in those in good condition occurred from peritonitis caused by the bacillus proteus vulgaris. Bacteriological examination of suture maternal dressings, and instruments failed to disclose the source of infection.

With the other fatal cases the toxemia of pregnancy in its various phases was the cause of death in by far the greater number of cases. Degenerative conditions of the heart muscle kidney and liver were the principal visceral lesions in these cases. Among those dying of infection the number was relatively but a small proportion of the whole and of these infections pulmonary infection by the pneumococcus or the mixed infection of catarrhal pneumonia and acute pulmonary tubercular infection were the principal causes of death.

These patients were many of them brought by ambulance from tenements and were in various stages of exhaustion and infection. In many of them there was no time for adequate preparation. As regards the fetus there was no foetal mortality in any case in which the fetus was in good condition at the time of operation and those foetal deaths which occurred were the result of previous attempts at delivery or infection or malformation. Of especial interest to the writer are twenty four cases of placenta prævia without a maternal death.

DIAPHRAGMATIC HERNIA

By OTTO J. SEIBERT, M.D., CLEVELAND, OHIO

IF we carefully review the literature on diaphragmatic hernia we will readily find that this condition is not nearly so rare as has heretofore been considered. A diaphragmatic hernia has always been regarded as a surgical curiosity, perhaps chiefly because the condition has rarely been diagnosed prior to operation or post mortem examination. In a review of some 250 cases by Leichtenstein (1) in 1897 in only 5 cases was the diagnosis made before death.

If we consider the anatomical development of the diaphragm and the relation it bears to the abdomen and the viscera it will seem almost obvious that hernia of this type should be just as common as other abdominal hernia. The diagnosis has heretofore been difficult because of the lack of external manifestations and definite physical signs. It has frequently been found while operating for some entirely different cause but most often at necropsy where death may have been due to other causes or directly to the hernia (i.e. strangulation or incarceration of the stomach or gut or to intrathoracic pressure).

Diaphragmatic hernia may be divided into three distinct types.

True hernia Those having a distinct sac. These may be either congenital or traumatic.

False hernia Those without a sac. Most of these are traumatic.

Elevation This is not a hernia in the strict sense of the term but a doming or thinning out or the entire absence of a part of the diaphragm.

In view of the pathology of this condition certain signs in the examination of the chest, such as displacement of the organs of the chest, dullness on percussion gurgling etc. should be of value in making a diagnosis especially in conjunction with the subjective symptoms. However these signs have on some occasions only confused and have led to other diagnoses such as pleuritic effusion. O'Dwyer (2) of New York in 1890 reported a case of this kind finding a diaphragmatic

hernia of the small bowel while operating supposedly for a pleuritic effusion in a child 1½ years old. The following day he operated for the cure of the hernia but the child died soon after the operation. In recent years however the X-ray has been the means of diagnosing the condition prior to operation or autopsy and through it diaphragmatic hernia will in the future I believe become more and more a definite surgical condition rather than remain a surgical curiosity. A brief review of the literature of some of the more interesting cases or series of cases will I believe not be amiss.

As early as 1852 Mr. Lawrence (3) reported to the London Pathological Society a case of large eventration found at autopsy on a man who had died of pneumonia. In 1861 Hulier (4) reported to the same society a case of diaphragmatic hernia of the small intestine found at autopsy in a child 1½ years old that had died apparently from intrathoracic pressure. In the *Bulletin of the Anatomical Society of Paris* (5) for the year 1863 is found a report of a case in which autopsy showed that death had been due to strangulation of a diaphragmatic hernia of the large bowel. In 1907 Gordon (6) of British Columbia operated on a man 33 years old for what he thought was a pyloric stenosis and found the entire stomach in the chest-cavity. A gastrojejunostomy was done after replacing the stomach in the abdomen; death, however, followed three days later. No attempt was made to close the enlarged diaphragmatic opening. In 1897 Cordier (7) of Kansas City did an emergency operation for an acute bowel obstruction but was not able to locate the obstruction until after death at which time he found the entire stomach and large bowel strangulated in the chest-cavity through an opening in the diaphragm 3 inches in diameter. Death was caused by the strangulation. In 1914 Binnie (8) stated that there were only two cases of cures on record.

In 1915 Robert Klenboeck (9) presented a rather extensive classified review of the German literature, which in brief is as follows:

A. Cases where autopsy showed death to have been due to strangulation of bowel or stomach through diaphragm. There were 11 left-sided false hernias, 2 left-sided true hernias, 1 left-sided rupture of the diaphragm.

B. Cases where autopsy showed death to be due to strangulation of stomach with perforation into (a) the thorax—3 left-sided false hernias, (b) the abdomen—1 left-sided true hernia and 1 enlarged oesophageal opening with split in diaphragm.

C. Cases simulating gastric ulcer or pyloric stenosis. Death due to other causes. Eight false hernias and 2 true hernias.

D. Cases diagnosed *intra vitam* and confirmed at autopsy. One eversion, 3 hernias.

E. One case coming to operation with large opening in the diaphragm. Stomach partially in the chest-cavity. Reposition of stomach and closure of diaphragmatic opening resulting in clinical cure.

Perhaps the most recent report of a cure of this interesting condition is that of Balfour (10) in January 1916 of a case from the Mayo Clinic, Rochester, Minnesota. A tentative diagnosis of hernia had been made prior to the X-ray examination and later confirmed by the X-ray and this in turn at operation, at which time a radical cure was effected. This case was apparently of traumatic origin, trauma having taken place 4 years previously. There was a large tear in the left half of the diaphragm allowing the protrusion of both stomach and bowel into the chest-cavity, causing the displacement of heart and lungs, giving rise to rather definite signs on chest examination.

The cases cited are perhaps only a small percentage of those already reported. However in a review even more extensive than the foregoing two facts remain prominent, namely the extremely small number of cases recognized prior to autopsy and the still smaller number of cures effected. Diaphragmatic hernia will no longer remain a surgical curiosity as heretofore but with the

X-ray at hand will become an almost every day finding. For this reason the diaphragm will in the future become a more frequented field for the surgeon. Each case bears with it different points of interest and is therefore worthy of record. The history of a case, which I had occasion to operate upon early in December 1915 was of especial interest from various points of view and is in brief as follows:

Mrs. D. age 68. Family history negative. Previous personal history. Although she has had more or less stomach trouble all her life even in her early childhood she has never had any real severe illness and has enjoyed comparatively good health. She has had four children and the confinement with each of these was a long protracted one, the labor in each case lasting from 36 to 7 hours. From the first of these she dates her present trouble. This was about 36 years ago. From then on she began to have pain after eating with much discomfort, belching and sour stomach. She often vomited her entire meal, undigested, four or five hours after ingestion. In the last two years this train of symptoms has become exaggerated in every respect. The pain and distress after eating became more severe, seldom was she free from sour stomach or belching. Vomiting followed almost every meal and the vomitus was often of a brown color. In the last year the pain and discomfort after eating became so severe and the vomiting so regular that she became afraid to eat, although she always had a good appetite. She has lost approximately 35 pounds in weight in the last ten months.

On December 1 I advised her to come to the city for stomach analysis and X-ray examination. The physical examination at this time showed little except signs of great loss of weight. Although still a large woman the skin was loose and flabby. The heart and lungs were normal to auscultation and percussion. There was no displacement. Clinical diagnosis at this time was pyloric obstruction, in all probability due to a cancer. On December 1, having been prepared for a barium meal, she was sent to Dr. Charles Goodman for X-ray examination. This proved to be most interesting. Repeated attempts to get a shadow of the barium in the normal region of the stomach failed. However shadows of the barium in what appeared to be the duodenum were shown, but these were rather far to the left. At last a large plate showed a large blotch of the barium in its extreme upper portion and on close examination it was found to be above the shadow of the diaphragm. This gave Dr. Goodman the idea that her trouble might be in the oesophagus and not in the stomach. Pictures through the chest were then taken. All of these showed what appeared to be the outline of the stomach above the

Fig. 1. Showing the entire stomach in the posterior thoracic cavity behind the heart and dense fibrous band binding the pylorus and first portion of the duodenum to the margin of the enlarged esophageal opening.

Fig. 2. Stomach pulled through the hernia ring and attached to the abdominal wall by sutures.

diaphragm behind the heart with the greater curvature upward and the pylorus to the left. Another examination two days later showed the same results. The stomach analysis proved to be normal in every respect except for a faint trace of blood. This I think was due to the stomach tube which passed with difficulty after reaching a certain point.

On December 6 the abdomen was opened one inch to the left of the median line directly below the margin of the ribs and our X-ray diagnosis was readily confirmed. The duodenum was seen passing to the left and upward directly to an opening in the diaphragm large enough to admit the entire hand. The opening was to the left and posterior and proved to be the esophageal opening. The entire stomach was found in the posterior mediastinum directly behind the heart. An attempt was made to deliver the organ through the opening into the abdominal cavity but this could not be done. It was found that dense fibrous bands of adhesions were holding the pylorus directly to the margin of the ring. These bands were so dense and firm that they had to be cut. After this was done the stomach could readily be pulled through into the abdomen. Interrupted sutures of heavy chromic catgut were then passed through the margins of the ring so as to almost entirely close it. This was accomplished with great difficulty because of the depth and angle of the field and also because the movements of the diaphragm caused the liver constantly to slide over the ring but chiefly because of the

Fig. 3. Stomach herniated almost entirely through the diaphragm.

Fig. 4. Roentgenogram, teroposterior view (not touched). The stomach is to the left of the spine and appears to form a loop before the pylorus is reached. Just external to the pylorus is the shadow of the heart.

proximity of the aorta on the one side and the pericardium on the other. Before closing the abdomen I fixed the stomach to the abdominal wall with two chromic gut sutures. The patient has made rather uneventful recovery and since the fourth day after the operation has enjoyed three big meals each day. The X-ray examination since the operation shows the entire stomach below the diaphragm but still somewhat higher than is normal. This I believe is due to an excessive doming of the diaphragm since the operation, the withdrawal of the stomach from the chest cavity leaving scant space above it.

This case is rather unique in that although the entire stomach was within the thorax there was no displacement of the heart in any direction nor was there any respiratory embarrassment as possible result of pressure. It was apparently congenital hernia, although the difficult labor in each case on this point must not be overlooked as possible etiological factor.

In the surgical treatment of these conditions the route of operative procedure is of course a subject of great importance. The two cases found on record by Binnie as cured, were by the thoracic route. Hedenhede's case in Kienboeck's review as well as Balfour's case was by the abdominal route. There are certain factors in the thoracic route which make it more hazardous and a more difficult operation. It is a much more extensive operation requiring in many cases the resection of 3 or more ribs and in most cases intratracheal anesthesia. It is therefore a greater

Fig. 5. Roentgenogram oblique view. The stomach is above the diaphragm, the pylorus directed backward and down and just anterior to the spine.

shock to the patient. In the abdominal route the liver greatly obstructs the field but with suitable retractors this can be overcome. If the abdominal route is chosen I believe a sort of reverse Trendelenburg position (i.e. head high and pelvis low) will be of advantage in making the field more accessible. Whatever route is chosen the field is at best a difficult one because of the proximity of the vital structures and any new point in the technique or new method of procedure will be valuable.

CARCINOMATOUS DEGENERATION OF SEBACEOUS CYSTS

BRISADORI SILL MD FAC NE Y RK
Adjunct Asst. Prof. Surg. in the Coll. of Surg. N. Y.

SAMUEL BERKOWITZ MD NE Y RK
Surgeon in Charge, Dept. of Surg. in the Coll. of Surg. N. Y.

ALTHOUGH Stedwagon (1) and Ziegler (2) state that sebaceous cyst rarely undergo epitheliomatous degeneration Rucker and Schwalb (3) in a monograph on tumors of the skin reviewing the whole literature to date report on 43 cases of epitheliomatous degeneration of sebaceous cysts. The patient comprised 31 males and 12 females but mention of the sex of the remainder was not made. Rucker and Schwalb found that heredity played an unimportant role. None of the cases was congenital. They could ascertain no one exciting cause in one case trauma was mentioned as a predisposing cause while in another menopause.

The ages of the patients varied one patient was less than 20, 10 cases were 60 or more and 29 were in the fourth to the sixth decade.

The tumors usually grew slowly. Most of them were the size of a walnut some attained the size of a man's fist.

The predominant location of these tumors was the face. The tumors were located as follows: 8 had their origin in the meibomian glands of the lids, 6 were situated on the cheek, 7 originated from the skin of the nose, 3 from the skin of the forehead and upper lid, 7 from the back part of the scalp, 1 was situated in the skin at the inner angle of the eye, 1 from the skin of the back, 1 in the breast, 2 in the abdominal wall and 1 in the upper extremity.

There is no mention of spontaneous appearance of any tumor.

In 17 cases out of 41 ulceration apparently played an important part in the transition to epitheliomatous degeneration.

Bloodgood (4) in twenty years observed about 300 cases of cancer in accessible regions of the body such as the skin, subcutaneous tissue and mucous membranes of the mouth, tongue and lips. The author feels that

proper surgery in the precancerous stage can accomplish 100 per cent cure.

In order to understand the pathologic picture and clinical course of these growths a study of the embryology and histology of the sebaceous gland is necessary.

Histologically sebaceous gland or hair follicle gland and sebaceous gland are in close relation to the hair follicles in the corium (1). They consist of a secretory portion and a duct. The basement membrane of the gland is surrounded by dense connective tissue arising from the hair follicle or from the corium and contain the blood vessels, nerves and lymphatics. Upon the basement membrane are several layers of epithelial cells, the outermost resembling that of the rete malpighii. In this layer the cells are cylindrical and columnar toward the inner portion they become larger and more or less cuboidal or polyhedral in shape.

According to McCarthy (5) these glands originate from the stratum germinativum or germinating layer of the epidermis. Downward growth of these cells into the subcutaneous tissue is accompanied by differentiation into hair, sebaceous glands, etc. Each newly differentiated part retains a row of cells which corresponds to the embryonal stratum germinativum.

Pathologically the ordinary sebaceous cyst is a retention cyst and arises from the occlusion of the orifice of a sebaceous gland on the surface of the skin. There being no outlet the secretion of the gland continues to collect in the interior and forms a cystic tumor. These are usually located on the face and scalp but may occur on any part of the body.

In following the development of a sebaceous gland and the formation of a sebaceous cyst one can readily conceive by proliferation of the epithelial cells lining the cyst which correspond to the embryonal stratum ger-

Fig. Specimen No. 447 subcutaneous epithelioma basocellulare. This specimen shows the epithelial cell thin sheoli arranged in pseudopapillary form

minativum it may undergo epitheliomatous degeneration. This proliferation may be due to irritation from within (as in Case 2) or as the result of ulceration of the cyst (Cases 1 and 3).

Within a period of twelve months we have had two very striking examples of the great value of early and complete removal of sebaceous cysts of the scalp that had undergone malignant degeneration. A third case seen by one of us (Seff) which terminated in general carcinomatous and death of the patient showed the result of incomplete removal of the tumor.

CASE. J. S. male, age 5 years, admitted to the Beth Israel Hospital, November 7, 1909, with the following history: At the age of 2 he noticed small growth on the right side of the head which did not increase in size till he was 35 years of age after which it rapidly enlarged. The growth became inflamed by continual irritation from combing his hair and finally opened with the discharge of serosanguineous fluid and foul smelling cheesy

material. The tumor was removed and he was told that it was sebaceous cyst. Within six years he had three recurrences of the tumor at the site of the first operation, and was told each time that the growth was a sebaceous cyst. His history on admission was as follows:

Nine months after the third removal of the growth i. e. fifteen months before the patient came under our observation he noticed small growth in the same location, which gradually became larger and ulcerated. On examination there is a growth about the size of buttonnut with crater-like ulcerated appearance situated over the right parietal eminence. The edges are indurated and the characteristic sebaceous material extrudes from its surface. The anterior and posterior cervical glands are not palpable. A diagnosis was made of epitheliomatous degeneration of a sebaceous cyst. Under general anesthesia the tumor with the healthy skin and subcutaneous tissue for distance of about a quarter of an inch beyond the growth was excised. The edges of the wound were brought together and the wound healed by primary union.

Pathological report by Dr. E. Moschowitz—specimen 357 (Fig. 1)

Four sections were taken from the tumor proper

Fig. 3 Specimen No. 50-6 recurrence of subcutaneous epithelioma basocellulare. This specimen shows the same arrangement as specimen No. 4427.

Fig. 4 Specimen No. 451 epithelioma. A detailed description of this specimen is given in the text (Case 3).

the tumor with overlying skin from the ulcerated edge of the tumor and from the subcutaneous tissue beyond the margin of the growth.

The tumor is a subcutaneous epithelioma consisting of smaller and larger alveoli irregularly polygonal in shape with only a small amount of stroma intervening. The alveoli are filled with epithelium which is basilar at the periphery becoming more flattened and larger as we proceed to the central portion. The central portion of the alveolus is occupied by a necrotic finely granular material, shading gradually into the adjacent epithelium. Within this necrotic material are shadows of epithelial cells some of which show faintly staining nuclei. These necrotic areas stain profusely with eosin. In some of these areas may be seen cross sections of the hair.

The epithelium is irregular but regularly placed. There are numerous mitoses and an appreciable number of epithelial pearls. In that portion of the growth situated beneath the cutis there is a distinct zone of connective tissue intervening between the growth and the superficial epithelium. This is infiltrated with abundant round cells.

Diagnosis: Subcutaneous epithelioma with keratohyalin degeneration.

One year after operation the patient returned with

a recurrence situated just beyond the margins of the healed incision. The posterior cervical glands were enlarged. The patient was impressed with the grave danger of allowing the growth to remain in the presence of the enlarged glands but would not submit to another operation. The patient has since succumbed to general carcinomatosis.

From an analysis of this case it is evident that malignancy is apt to occur in a simple sebaceous cyst as a result of inflammation and continual irritation. Although the growth recurred four times the lymphatic glands did not become palpable until the last recurrence.

CASE 2. Patient M. M. female, age 23 years, came under our observation at the Beth Israel Hospital Dispensary, November 2, 1913. Six months previously (May, 1913) she noticed a small irregular growth on the forehead which was slowly getting larger. This tumor was not painful or tender to touch but annoyed her from a cosmetic standpoint. Her personal and family history had no bearing on the present condition. Examination revealed a small irregular swelling situated on the

glabella about the size of an almond which was attached to the skin at one point. The tumor was movable over the underlying tissues. It was somewhat irregular in outline but felt smooth. No submaxillary glands were palpable. A pre-operative diagnosis was made of simple sebaceous cyst. Under local anesthesia (novocaine 5 per cent) the tumor was easily shelled out (the wound closed and the patient advised to return periodically for observation. The tumor on cross section showed a granular mulberry like tissue enclosing sebaceous material in the center.

Pathologic report by Dr. Eli Mouchon—specimen 4427 (Fig. 2).

The specimen represented a isolated tumor. The alveoli vary markedly in size and are irregular in shape and distribution. The microscopic field is apparently evenly divided between alveoli filled with well-staining epithelial cells and alveoli containing a small number of peripheral epithelial cells enclosing masses of necrotic hyaline tissue.

Alveoli containing cells only. These alveoli are small. The epithelial cells within these alveoli are two small and arranged in a pseudopapillary form. The nuclei are spherical, uniform in size and rich in chromatin. There is a well-developed arrangement of prickles.

Alveoli with cells containing hyaline necrotic material. These alveoli are as a rule much larger. Along the periphery are epithelial cells of greater or lesser thickness. These cells are spherical at the base, gradually taking a tetrahedral arrangement as we proceed toward the center until they merge gradually into the necrotic hyaline tissue. Within the hyaline necrotic tissue, especially at the periphery, are shadows of epithelial cells often containing nuclei which are more or less faintly stained. The necrotic tissue is arranged in cords, representing the early epithelial arrangement before degeneration takes place.

The connective tissue stroma is small in amount and reveals slight infiltration with round cells.

Diagnosis: Sebaceous epithelioma, basal illu-

The patient, although advised to report at stated intervals, did not return till seven months after the tumor had been removed. The tumor then a recurrence of the primary skin which was about the size of a hazelnut. As a result of the persistence with Case 2, we decided to make more extensive removal of the surrounding tissue. Under local anesthesia the growth was removed with the adjacent skin and subcutaneous tissue for a distance of a half inch. The subcutaneous tissue for a very short distance beyond the growth also had the same peculiar mulberry like appearance as was seen in section of the tumor.

The microscopic examination of specimen 56 the recurrence was reported by Dr. Mouchon as being identical; appearance with the original growth (Fig. 3).

The patient has been entirely free from any

recurrence since the last excision of the tumor and the surrounding tissue and is in good health almost two years after the second operation.

Case 3: A. M. E. male, age 47 years, was admitted to the Beth Israel Hospital August 20, 1914. In May 1914 he complained of a small growth about the size of a hazelnut located in the right temporal region. Repeated manipulation by his barber caused an inflammatory reaction and the growth began to discharge a thick cheesy and foul smelling material. Two unsuccessful attempts were made by his family physician to remove the growth under local anesthesia. It continued to discharge and grow larger. The patient was told that the growth was a sebaceous cyst. On examination we found a grayish white, lamellated, pushed out ulcer about the size of a five cent piece, with inflamed edges and a surrounding flaky discharge. There were no pre-auricular nor cervical glands.

On August 13 the growth was excised together with the skin and adjacent subcutaneous tissue for a little over an inch beyond the distal edge of the ulcer. The wound healed by second intent. Recurrence was prevented.

Pathologic report by Dr. Mouchon—specimen 536 (Fig. 4).

Specimen consists of many irregular alveoli filled with squamous epithelium, many of them intercommunicating. The center of many of these alveoli contains epithelial peripheral prickles which are common. The stroma is small in quantity and consists of loose fibrous tissue infiltrated with many round cells. The circumference of the tumor is surrounded by squamous epithelium covered by a horny layer. Toward one side of the specimen this layer represents a perfectly normal skin. Around the rest of the circumference this layer shows great hypertrophy and dips into the stroma communicating with many of the epithelioma. In all of this there is evidence of ulceration.

Diagnosis: Epithelioma.

Fifteen months after operation the patient writes that there is no evidence of any recurrence or enlargement of the neck.

From the history we infer the former existence of a sebaceous cyst although at the time the patient came under our observation an epithelioma was really diagnosed.

CONCLUSIONS

1. The origin of malignant changes in simple sebaceous cysts can readily be traced by a study of the embryology of the sebaceous glands.

2. Malignant degeneration of sebaceous cysts may occur at any period of life.

3. Local irritation is an important exciting factor in the malignant degeneration of a simple sebaceous cyst.

Fig. 1. Root cyst involving the left maxillary sinus.

serted through the oral incision. The gauze which extends some two inches past the protective covering may be moistened with hydrogen peroxide and lubricated with sterile vaseline. It is lightly packed against the walls of the cavity maintaining in place any mucous membrane flaps which may have been preserved. The oral incision is closed with interrupted fine catgut sutures. The drain should be removed from the nose in 24 to 48 hours. This may be followed by slight bleeding. A few post-operative nasal irrigations may be advisable.

This method of closure has been most successful the incisions healing *per primum*. In none of the cases of maxillary sinusitis did the wound re-open as is reported by Dean, who for this reason has substituted silk worm gut sutures tied over rubber tubing. The excellent union is no doubt due to the fact that the incision is made at the reflection of the mucous membrane, which is at a considerably higher level than that described in textbooks. At this level the submucous tissue is greater in amount and therefore more easily approximated. In one instance

following the removal of an extensive odontoma the anterior end of the oral incision reopened communicating with the floor of the nose (Case 3). Attempt will be made to close this at a later date.

CASE REPORTS

CASE 1. R. V. female, age 26, complained of a swelling of one year duration beneath the left eye. The enlargement had been gradual and unaccompanied by pain. There was a history of chronic nasal discharge and the nasal examination was negative. In addition to the tumor which was firm and crepitant and situated above the cuspid, bicuspid and first molar teeth on the upper left side examination of the mouth showed the absence of the upper left first bicuspid. The patient did not know whether it had erupted and had been extracted or not. The roentgenogram (Fig. 1) did not reveal the missing tooth nor was it found at operation the tooth being root-cyst. It was removed as described later technique. The post-operative course was short requiring practically no treatment.

CASE 2. E. C. male, age 3, had a dentigerous cyst operated upon three years previously and the cavity had been kept open externally and irrigated for 4 years before it closed. One month before presenting himself there had been acute pain, swelling and rupture followed by a discharging sinus in the left cheek. There was some nasal discharge. Roentgenogram (Fig. 2) showed a tumor and infection of the maxillary sinus. Operation disclosed large odontoma involving a considerable portion of the alveus. The tumor and the diseased mucous membrane of the maxillary sinus were removed. Intranasal drainage established in the usual manner and the oral incision closed with catgut. The sinus in the cheek with a portion of the scar of the previous operation, was excised and closed with fine silk. The post-operative course was uncomplicated.

CASE 3. M. B. age 3, complained of lump in her right cheek of 4 months duration and of somewhat rapid growth. This had appeared during the latter part of pregnancy which accounted for her delay in presenting herself for treatment. The growth had been slightly tender but was not accompanied by pain. Examination showed large fluctuant swelling in the right superior maxilla, measuring about 5.5 cm. and extending from the right second molar to the left central region. There were many carious roots present and the right central incisor was missing. The floor of the nose and the inferior turbinate were displaced upward and medially and there was a small perforation of the septum. The roentgenogram (Fig. 3) showed a mass in the right maxillary region and the unerupted incisor. The Wassermann reaction was negative. At operation the cyst was found to extend to the posterior limits of the maxillary sinus.

FIG. 1. Recurrent follicular odontoma of the left maxillary incisor.

destroying a large portion of its anterior and lateral bony walls. Anteriorly it extended beneath the floor of the nose and vomer to the left side. The imperfectly developed incisor was located high up beneath the vomer and removed the cyst wall was dissected free with considerable difficulty and removed. A large cavity remained which was drained by removing the part of the interior nasal wall and opening into the floor of the nose. The oral incision was closed with catgut. On a unit of the extent of the cavity packing was continued for several weeks along with irrigation of potassium permanganate solution and salt solution. Three months later the deformity had practically disappeared there was no discomfort or discharge and the maxillary sinus was clear on roentgen illumination.

CONCLUSIONS

1. Odontomata of the upper maxilla which involve the maxillary sinus to any ex-

FIG. 2. Extent of the maxillary sinus and palate and the right central incisor which had been removed. The left central and right lateral incisors are visible.

tent are best treated by nasal drainage the oral incision being completely closed following the removal of the cyst wall.

2. By this procedure the post-operative course is greatly shortened the discomfort, pain and dread of the repeated oral drainage are avoided.

3. Any ill effect upon the nasal mucosa are negligible the swelling and irritation following the treatment being of short duration.

DEPARTMENT OF TECHNIQUE

AN OPERATION FOR THE CORRECTION OF DEFORMITY FOLLOWING CHOPART'S AMPUTATION OF THE FOOT¹

B. JOSEPH F. SMITH, M.D., W. M. A. W.

CHOPART'S amputation of the foot is open to the well known objection that it removes the front of the foot in such a manner that the weight bearing bone—the astragalus—is deprived of the support normally afforded it by the front of the foot and tends to be pushed forward against the cicatrix, producing painful tension and pressure. Besides, the tendo Achilles unbalanced by the action of the dorsi flexors, raises the heel, thus rotating the astragalus forward and tending to protrude the latter bone still more against the cicatrix. The elevation of the heel by the unopposed action of the tendo Achilles may even produce such marked back

ward tilting of the stump that the cicatrix becomes part of the weight bearing surface, thus adding still more discomfort in any attempt to walk or bear weight upon the stump. Division of the tendo Achilles gives only temporary relief and the procedure of implanting the dorsi flexor tendons into the plantar flap does not always suffice to overcome the difficulty because in this implantation it is difficult to secure the necessary leverage to give the tendons action.

In spite of the objections to Chopart's amputation, it is still described in all the textbooks and is apparently the operation employed rather frequently in railway surgery.

Fig. 1. Ray print showing position of bones of stump after Chopart amputation. Fig. 2. Approximate line of incision through astragalus and on calcus for correction of deformity.

Read before the Chicago Surgical Society, April

Fig. 1. A print from a postoperative film of the tumor after resection.

Following Chopart amputation Pirogoff operation has frequently been done for the correction of the deformed and painful stump. The procedure herein described was carried out as a substitute for the Pirogoff operation in the correction of this condition and has not been found in the literature at hand although it may have been previously described and carried out.

A. V. all said employment of the wrist are in the spring of 95. A hunt of the wrist described above resulting from a Chopart amputation carried out for crushing injury of the foot (wound in a blow) some about a year before. There was marked back and tilting of the stump rotating the tenor surface downward so that the scaphoid formed part of the weight bearing surface of the foot. The scar had become red and tender and the man had been obliged to discard an artificial foot which he had been wearing. The X-ray plate showed marked forward tilting of the scaphoid and tilting of the os calcis. It was impossible to ascertain whether or not any attempt had been made to anchor the dislocated os calcis.

Instead of making Pirogoff amputation the following procedure was carried out. A preliminary subcutaneous incision along the tendo Achilles was done and the os calcis was freed from the os alibi. An incision on the lateral aspect of the stump parallel with and about 1 inch above the sole of the foot was then made, the motion being carried down to the bone. After the flap had been reflected the scaphoid and the talus were sawed through along the lines A-B-F-G, the upper part on the os calcis and the lower portion of the head of the scaphoid being freed and removed. The os alibi then pushed forward under the scaphoid so that the scaphoid surface were approximated. The bones were drilled and the bones secured in position with small bone nails. The wound was closed with sutures. A light plaster cast with the patient in a prone position was applied. During the first week the cast

Fig. 2. The same patient after Pirogoff amputation.

remained in the position of slight inversion and pronation.

At the third month the patient walked without a shoe, that is, that the patient had a good shoe made which enabled him to walk without the support of any device, not that he had been in the position of the foot for the first two months, but that the patient had recovered from the deformity. The X-ray plate of the foot after the operation showed about 4 months after operation and the patient was able to walk without the aid of the stump.

The advantages of this procedure over the Pirogoff amputation are the following:

1. It is much simpler and more easily executed.
2. It preserves a larger area of the sole of the foot as a weight bearing surface—a matter of great importance in these cases.
3. It preserves the ankle joint and allows some degree of mobility to the stump.

DISCUSSION

Dr. Samuel C. Lister, Jr. In the case here the result, such as has been described, I should say that this operation is an improvement on Pirogoff. I find that Pirogoff amputation gives better result than an amputation of the joint of the lower and middle third of the leg and Dr. Smith operates I would regard as an improvement over the Pirogoff.

In the primary Chopart amputation in this case, we do not know whether the tendons of the flexor of the foot were bored. That I would make an important point in Chopart amputation. The supposed action of the strong flexor muscles attached to the tendons of the flexor of the foot bend the foot downward and make the entire part of the foot bend downward and a foot-drop a fibrous process of the dead atrophic plantar muscle results. That Dr. Smith obtained in this case before operated him but if he used the tendons of the flexor of the foot, he would be able to perfect a lot of the ankle and the patient would get a good result.

THE TREATMENT OF FRACTURES BY NAIL EXTENSION

A PRELIMINARY REPORT

B. FREDERICK G. DYAN, M.D., CHICAGO

THE purpose of this paper is to make a preliminary report upon a series of cases treated by the nail extension known as Steinmann's method. The rapid development of the treatment of fractures and the bewildering rapidity with which new methods have been proposed within the past few years prove that the treatment of fractures is still in the developmental stage, and also demonstrates a renewed interest in this subject which roentgenology has brought about. If one may take Hoffa's statement as correct that two-thirds of all invalidism is due to fractures, it is only fitting that a subject of such great economic importance should receive a proportionate share of attention.

Possibly the greatest interest in the operative treatment of unreduced fractures was stimulated by Lane. He leads that school which believes in an immediate complete anatomic restitution by open operation. The opposite school is led by Lucas Championniere who believes that fixation of the fragments is not the first consideration but preservation of function that to be obtained by immediate mobilization and massage. As Steinmann has pointed out each of these extremes is probably wrong, the ideal method being one which would include the good features of the early anatomic restitution and also mobilization of neighboring joints.

It is unnecessary to enumerate the vast number of methods used in the closed treatment of fractures. This subject may be dismissed with the observation that in many cases these old time honored methods suffice to bring about good functional and anatomic results. The open operation which has literally been done to death in the last five years, especially in the hands of those who are not equipped either by training or environment to properly execute the technique involved in a procedure in which the element of infection is so great a hazard, requires only the statement which I believe will receive the support of every experienced surgeon that open operation must necessarily carry with it the danger of infection. Infection is frequently disastrous to the limb and often to the life of the patient. Therefore, open operation must be strictly reserved for that class of cases which is not amenable to other methods of treatment.

As Anschuetz observed the nail extension of Steinmann is to be regarded in the light of a compromise measure between the frequently inefficient closed method and the hazardous open operation. The nail extension method was not original with Steinmann who got his idea from the Malgaigne hook so familiar in the pages of textbooks on surgery. This apparatus resembled nothing so much as a pair of ice tongs. Heinecke later invented an instrument which was quite similar in the blades, handles, and direction of pull to an obstetric forceps.

Codivilla in 1903 used an extension by means of plaster of Paris which adhered well in many cases, but the tendency of the plaster of Paris was to produce a pressure necrosis.

From these methods Steinmann developed his procedure which he described as a method of extension which exerts a continuous traction exclusively by the aid of nails or screws which are driven either in or through the bone whenever possible through the lower fragment. The original method was to drive a nail transversely through the lower fragment. This later was modified and two nails were used, one on each side being partially driven through.

The method of the introduction of the nail has been modified at various times. First the hole was drilled through the bone and the nail introduced through this drill hole. Another method was by preparing a nail with a square head which could be received into a brace and bored through exactly as a carpenter might with a brace and bit. This method is probably the best. However it is quite possible to introduce the nail in the first manner by simply driving it through with the hammer.

Various types of nails have been used both by Steinmann and other operators, but experience has shown that the simple round nail with the sharp point answers every purpose. A special extension apparatus to be applied to the nail itself was devised by Steinmann, but the copper wire loop is quite as useful.

The point of introduction of the nail is of great importance. It is a cardinal principle in the treatment of fractures to postpone operative procedures until the inflammatory reaction or hematoma has at least partially subsided. Thus

FIG. 1. Showing patient in bed with horizontal line indicating point of nail through skin.

holds true equally well for the nail extension because the introduction of the nail necessarily converts a simple into a compound type of fracture and adds a foreign body. Therefore in selecting the point for the introduction of the nail avoid if possible areas in which the soft parts have been traumatized and endeavor to utilize a portion of the bone which will not invade the medullary cavity. A situation close to the epiphyseal line is ideal except in the case of children and young adults in which epiphyseal ossification is incomplete. Furthermore it is desirable to avoid injury to the joint capsule which can usually be done by a consideration of the anatomy of the parts before introducing the nail.

The technique of the procedure is as follows: The skin is disinfected in the usual way. A small tenotomy incision is made down to the bone. Usually it is possible to select a site in which the bone is almost subcutaneous. The edges of the small incision are held apart by suitable retractors; the nail grasped in a heavy forceps is introduced through the tenotomy incision until it comes in contact with the resisting bone. The point of the nail is then given a suitable direction and forced through either by the hammer, the hand drill, or an electric motor. It is a good plan to have an assistant make pressure upon the opposite side of the bone with a wooden block covered by sterile linen to receive the shock of the hammer blows or the drill force. When the skin is seen to be elevated upon the opposite side a second small incision is made and the nail forced through further until an equal part protrudes upon each side of the bone. A collodion dressing is then put upon each wound. This is covered by sterile dressings, a sterile copper wire loop attached and finally the limb held in place by a sterile roller bandage.

FIG. 2. Patient in bed and horizontal line indicating point of nail.

In our work this procedure has always been carried out under general anesthesia. However Steinmann, Anschuetz and other report success with local anesthesia it being claimed that the only pain arises from the soft parts and periosteum.

Traction is then applied to the wire loop by means of a rope which is run through a pulley and a suitable weight attached the amount of traction being controlled by frequent X-ray pictures. The direction of the traction can always be modified in such a manner as to exert the pull in a line continuous with the long axis of the fragment involved.

It is unnecessary to take up in detail the various situations in which a nail may be introduced. Suffice it to say that it can be used both in the upper and lower extremities. However its chief field for use is in the lower extremity because of the necessity of overcoming the shortening coincident upon the contraction of the heavy muscles of the thigh and leg.

The nail may also be used as a lever. This may be accomplished in one of two ways. For instance in outward rotation of the lower extremity in fractures of the neck of the femur in which suitable inward rotation cannot be obtained. A nail driven into the great trochanter of the femur in a line parallel to the long axis of the

Fig. 3. Roentgenograms of Case before and after application of nail extension for fracture of the right tibia and fibula.

neck of the femur and attached to a rope and weight running through a pulley will tend to bring about and maintain overcorrection of the outward rotation.

Another method of using the nail as a lever is by hanging a weight on one or the other end of the protruding nail thereby bringing about rotation in the direction desired. The duration of the traction is governed by the amount of correction of the pre-existing deformity. The optimum time is eighteen to twenty-one days. During that period a certain degree of pressure necrosis takes place and this is usually more than enough time for the correction of the overriding of the fragments if sufficient weight has been applied. The pressure necrosis makes the removal of the nail easy because of the increased caliber of the nail hole. The nail may remain *in situ* however for a considerably longer period of time depending upon the judgment of the surgeon. However the danger of infection necessarily increases with the duration of time. One case was reported in which because of the intensity of the traction the nail cut through the os calcis, in which it had been introduced too near the plantar surface exactly as a dull knife would cut through butter. The nail was removed, no infection took place and healing occurred without complications.

The intensity of the traction is determined by the progress with which the deformity is overcome. Ordinarily the discomfort resulting from any traction necessary to overcome the deformity is not great and speedily diminishes.

Lateral dislocation of the fragments may be treated with the extension in place by means of

Fig. 4. Roentgenograms of Case showing position of fragments before application of nail extension and after.

a loop of adhesive passed around the offending fragment and attached to a weight and pulley. Dislocation of the fragments in the longitudinal direction with complete separation of the fractured ends is possible because of the great traction exerted and must be carefully watched by the roentgen control.

It is perfectly possible with the nail extension to keep up functional treatment. This is a great point in favor of this method. Another advantage is in the treatment of compound fractures because of the fact that the nail introduced frequently at a point rather remote from the place of fracture it is possible to begin the treatment before the infection has subsided thus gaining much time. Furthermore it gives perfect access to the wound and thereby permits of frequent dressings. It is especially indicated in those types of fracture which are not recent and which are complicated by considerable overriding. The longest time at which the method has been used for this class of cases is in one reported by Anschuetz, in which the nail extension was applied to an ununited fracture 142 days after the accident, and a good functional and anatomic result was secured. In alcoholics and demented individuals it has also the advantage over many methods that it cannot be removed by the patient.

Among its disadvantages may be mentioned first the danger of infection. However as the nail is frequently introduced through the os calcis, a bone which has no medullary cavity and

Fig. 5. Roentgenograms of Case 3 showing fracture of both leg before and after application of nail extension.

which, because of that fact, is hard to infect, the danger from that source in fractures of the leg is very slight. It is true that the danger increases with the introduction of the nail in the long, hollow bones, but if the precautions outlined by Steinmann are borne in mind, this is relatively light.

A second objection is the apparent brutality of the method. This is altogether theoretical and not real. Our experiences with a number of cases so far have demonstrated the fact that there is no more discomfort with the nail extension than with the Buck's extension in many cases, not as much. It is true that fatalities have resulted from this method, as from any other open method of fracture treatment, but the proportion of infections resulting from the nail extension as compared to the radical open operation we believe is very small.

Injuries to the soft parts may result from the introduction of the nail. In Case 3 of our series, a nail perforated the posterior tibial artery. The incision was scarcely enlarged, the vessel picked up and ligated, and no unfavorable results occurred. This has occurred in a few reported cases, but in no instance was any permanent damage caused. Decubitus in the region of the nail hole has been reported but did not occur in any of our cases. Because of the intensity of the traction exerted, it is possible to cause an overcorrection, that is, a separation of the fragments in a longitudinal direction. This may be controlled by frequent X-ray examinations and is easily reduced by lessening the amount of traction. The enormous traction also may be utilized for the lengthening of the soft parts

where contraction has resulted from improper reduction and immobilization at the time of the injury. This is a great help in the treatment of old fractures.

Lateral dislocation is frequently overcome simply by the traction in the direction of the long axis of the limb, the tendency being for displaced fragments to fall into position when the intensity of the traction is sufficient to overcome the overriding.

It has been argued by some that the method delays union because of the tendency to separate the fragments. This is a purely theoretical objection because the traction is released as soon as the deformity is overcome and a permanent fixation dressing such as a plaster cast is immediately adjusted. We have not observed this in our cases.

Among the advantages of the method may be mentioned first that from a mechanical standpoint no other procedure can be expected to produce as strong traction. It is not more painful to the patient than less efficient methods. The traction is exerted directly upon one fragment and not merely upon the soft parts. The traction exerted by the familiar Buck's extension is exactly comparable to making traction upon the arm by pulling upon the coat sleeve. There is no direct pull upon the fragment.

In those fractures of long bones in which one fragment is very small, as in fractures of both bones of the leg near the ankle, it is of great advantage to apply traction in such a manner that only a small area is needed for the attachment of the traction apparatus. No plan has yet been devised which requires so little space for its

attachment as does the nail extension of Steinhmann. This is of further importance from the fact that it permits free access to open wounds in compound fractures.

I wish to refer to a few case histories of patients treated in Cook County Hospital by this method.

CASE 2. The patient male suffered fracture of the right tibia and fibula about hand breadth above the lower articular surface of the tibia, also fracture of the internal malleolus. The fracture of the tibia was spiral and there was an overriding of the fragments of about an inch and half. Repeated attempts at reduction under anesthesia by various methods failed to reduce the fragments.

December 8, 1915 under ether anesthesia and most careful asepsis, a small tenotomy incision was made over the os calcis on its inner side. At this point a wire nail six inches long was driven through the bone transversely to its long axis, and at this point where the traction was applied could exert pull on the lower fragment of the tibia, bringing it into alignment with the upper fragment. The nail protruded about two inches on each side of the wound. The wound was sealed with collodion and sterile dressing applied. A copper wire loop was now attached to each end of the nail and extension made by means of a rope and pulley attached to this copper wire loop.

Traction was kept up for eighteen days. At which time the nail was removed, the roentgenogram showing complete reduction of the overriding. There was little lateral displacement. A plaster cast applied for three weeks more. At the end of which time the patient left the hospital with splendid functional result and no shortening. There was no infection and the patient complained of no pain (Fig. 5).

CASE 3. On December 8, 1915, patient presented himself to the County Hospital with fracture of both bones of the right leg at about the junction of the lower and middle thirds. There was overriding of the fragment of about one inch. Two attempts were made under ether anesthesia to reduce the deformity but were unsuccessful.

On December 3, under ether anesthesia and careful asepsis, large incision was made transversely through the os calcis after making small tenotomy incision on each side. A cotton block covered by sterile towel was braced against the opposite side from which the nail was introduced in order to take up the shock caused by the hammer blows. The nail was introduced so that an equal amount protruded on each side of the leg. The wound was then sealed with collodion and sterile dressing applied. A copper wire loop was attached and held in place with rubber bandage.

The traction was left on for three weeks at the end of which time the roentgenogram showed perfect anatomic reduction. The nail was removed, the wound sealed with collodion, and plaster cast applied for three weeks more. At the end of this time it was removed, and examination showed strongly united bones. There was no infection in this case and the patient complained of no pain (Fig. 4).

CASE 4. A fifteen-year-old girl jumped from the third-story window of the County Hospital and sustained a fracture of both bones of both legs (Fig. 5). On the right side the fracture was compound. On the left side there was separation of the lower epiphysis of the tibia. This girl was very much below par mentally and at the time of her attempt at suicide she was being treated for some drug habit. For three weeks subsequent to her injury she was treated by placing both legs in fracture boxes

and dressing the wound daily. She would allow no attempt to be made at reduction. Consent was obtained from her parents to use the nail extension.

She was anesthetized and the nail introduced the usual way on the side of the compound fracture. Upon the opposite side an assistant was allowed to introduce the nail but missed the bone and drove it through the plantar fascia and peroneum as was shown by an X-ray examination at a later time. Considerable trouble was experienced with this girl, who complained of suffering great pain both legs at the point of entrance of the nail and color as less than her complaint when the X-ray revealed one nail in the plantar fascia. This nail was then removed and no further attempt made to apply the nail extension on that leg. However by cutting and breaking she finally induced a flow the traction to be made upon the right leg. The nail remained in place for four weeks upon this side because of the fact that there were four points upon which she could allow no right to be attached to the rope. Upon other days she could allow eight or three or four breaks, depending upon her humor. The second site of the compound fracture healed kindly, the roentgenogram showed complete reduction of the overriding of the fragments and the patient obtained splendid functional result upon this side.

On the left side she was able by anesthetizing her again to get the fragments into fair good shape and broke them by means of the nail. The nail allowed to remain on for four weeks on each side.

The girl now has a functional limb. Upon the side on which the nail extension was used there is no apparent deviation from the normal. Upon the opposite side slight deformity is present but she is undoubtedly able to walk about limp. In this particular case I believe there was no other way in which this fracture could have been so successfully treated.

CASE 5. A man twenty-seven years of age came to the County Hospital in January, 1916. He had just spent four weeks in another hospital under treatment for fracture of the middle of the femur with overriding. This was treated in the ordinary way by simple traction extension. A roentgenogram showed after four weeks that there was no reduction of the deformity and the patient presented himself for treatment.

He was an intelligent man and he explained to him that he had the choice of two methods of treatment, one the open operation with the bone transplant, or traction by nail extension. After some lying he consented to be the fracture treated by the nail extension method.

He was anesthetized and the lower end of the femur was prepared in the usual way.

A small tenotomy incision was made low down over the external condyle, a point where the bone is almost subcutaneous. The nail was driven through until it emerged through the internal condyle. The wound was sealed with collodion dressing, a wire loop applied and traction made with the limb resting upon double inclined plane in such manner that the line of traction was direct line with the long axis of the femur. In order to bring this about, a piece of two-by-four was made fast to the foot of the bed so the same side as the fractured limb. A cross arm was nailed upon this and pulley attached to the cross arm about foot from the main piece. This enabled him to be in bed with the limb in position of moderate abduction, as this position is most comfortable. A weight of five and some times six bricks was attached for three weeks. The patient at first complained of some pain in the region of the fracture. It was noted in roentgenogram made at the time of his admission that there was considerable callus at the point of fracture and an overriding of about an inch.

The pain soon subsided and the patient expressed himself as being more comfortable than he had previously been with the Buck extension applied.

At the end of three weeks the nail was removed, the twenty-eight inch long board that the extremity had been in was removed. The lower extremity was then put in a cast reaching from the axilla down to the toes and taking the opposite limb as it was the knee. At the expiration of six weeks this cast was removed and it was found that the patient had complete bony union of the fracture with no deformity. Measurement showed the circumference of the leg to be less than half an inch. There was no infection at a time and the patient did not complain of any severe pain.

CASE 5. A male aged thirty-nine sustained a comminuted fracture of the middle of the tibia with about an inch and half overriding of the fragments. An attempt at reduction was made by traction, repeated a plaster cast which had been applied to the tibia and a weight attached to the rope. On examination of the distal tibia showed a red union of the distal tibia.

At that time under the anesthesia, nail was driven through the os tibia and weight attached in the manner already described. At the end of sixteen days, fifteen grams showed that the distal tibia was perfectly united over os tibia except that there was a little backward bending. This was easily corrected by pulling up under the portion of the bone. The nail was removed and the limb put up in a plaster cast. Union has not yet occurred.

CONCLUSION

Advantage 1. It is less laborious than the radical open operation.

It enables the surgeon to exert the maximum amount of traction while using the minimum area for the attachment of the traction apparatus.

It will bring about a reduction of the deformity in old cases where other methods fail.

4. The technique is not difficult and can be mastered by anyone. Therefore the method is practical and can be used by the entire profession.

It gives access to wound in compound fractures permits frequent dressing and dressings away with unclean infected traction apparatus.

Disadvantage 1. Apparent brutality of the procedure. This is not real however as the patient suffers no more by this traction than by any other method.

Danger of infection. This is less than the danger of an open radical operation.

Hemorrhage. This may occur but can always be readily controlled by enlarging the incision and tying off the bleeding point.

CONTINUAL STOMACH LAVAGE AND CONTINUOUS HYPODERMOCLYSIS IN PERITONITIS PERSISTENT VOMITING WITH DEHYDRATION AND DILATED STOMACH

WITH A DESCRIPTION OF A MODIFIED STOMACH TUBE

By ALLEN B. KANAVEL, M.D., CHICAGO

THE separate or combined use of continual stomach lavage and continuous hypodermoclysis in the dehydration and toxæmia incident to peritonitis has proved itself of such signal benefit that it would seem to be worthy of wider appreciation. It has also been used with great satisfaction in persistent vomiting of any type in dilated stomach after operation, and in similar states while the continuous hypodermoclysis in addition to being used in combination with the gastric lavage may be used in dehydration and toxæmia from any cause. To make the procedure available certain changes in the ordinary technique have been devised.

STOMACH LAVAGE

For urgent purposes a stomach tube modified from the Einhorn and Rehuss types has been devised. This modification is necessary since we wish a tube that can be inserted in the stomach

and left in position days if necessary; moreover the tube should be one that can be introduced without the active co-operation of the patient. Since it should be available even though the patient be nauseated and vomiting continually or be fully anesthetized.

The tube and its carrier are constructed as follows. The bulb is of the same size as the Rehuss bulb except that the lumen of exit is larger and it is so constructed that it is impossible for the wire carrier to slip out. The rubber tubing is of the same size as the Rehuss tube but only 30 inches long being attached to a second heavier tube 12 inches long by a screw lock. A carrier of piano wire is made to fit the first tube so that it can be introduced without difficulty. The second tube is attached after the removal of the carrier and the contents of the stomach aspirated or siphoned off.

If the patient will swallow the tube the lumen

Fig. Stomach lavage tube, bulb and wire carrier

of exit of the bulb being larger than the Rehfuss tube the stomach contents can be aspirated with greater freedom and the mucus interferes less. This latter is of considerable importance in post-operative lavage when the mucus is generally considerable and interferes even with this tube at times. It will be seen that the bulb is so constructed that the point of the wire carrier cannot slip out of the bulb and injure the stomach. Owing to the shortening of the rubber tubing, there is less probability of the collapse of the tube upon suction and there is less difficulty in removing the carrier. This latter procedure is also aided by having the patient throw his head back thus lessening the sharp angle in the tube.

The tube described has proved of signal benefit in the vomiting of peritonitis or persistent vomiting from any cause as well as being of great aid in the routine examination of stomach contents for diagnosis. In the former instance the tube is either introduced by the surgeon, or is swallowed by the patient. It is then attached to the chin by a piece of adhesive plaster and may be left in for days. In the regurgitation incident to peritonitis, the stomach contents are aspirated every half hour to an hour and at regular intervals the stomach is washed out by injecting soda solution, or other liquid, through the tube and aspirating it. Between the washings the end of the rubber tube attached is placed in a basin with the end covered by fluid so that a continuous siphonage takes place. The retention of the tube is without discomfort, while the absence of stomach distention and vomiting gives the greatest relief to those distressed patients.

Fluid may be left in the stomach or medication given if desired. In one patient with peritonitis who was apparently moribund the tube was kept in the stomach four days and the patient did not vomit after the treatment was begun although he had been regurgitating large amounts previously. In addition to being used in peritonitis cases it has been used in persistent vomit-

ing from any cause, as paralytic ileus, gastritis, toxicemic vomiting etc. In such patients after washing the stomach for a day or two small amounts of liquid food are introduced and if subsequent suction shows that the food is being absorbed or is passing the pylorus, feeding is increased. Thus without discomfort to the patient we give food at the earliest possible moment.

If the tube passes the pylorus, as it may do upon the resumption of the normal stomach peristalsis, the duodenal contents are then aspirated which may be of benefit in some cases. It has occurred to me that it might be possible to carry the tube through a gastro-enterostomy, opening at the time of operation and thus aspirate intestinal contents or introduce food. I have not attempted this, however.

CONTINUOUS HYPODERMOCLYSIS

In patients suffering from dehydration from any cause or from toxæmia, the administration of large amounts of normal saline during several days has long been recognized as of great value. The administration of this at stated intervals, calling for the reinsertion of the hypodermoclysis needles, thus distressing the patient and entailing much work on the part of the surgeon has militated against its more common use. To obviate this the following technique has been satisfactory. The ordinary hypodermoclysis set has been used with the exception that the needles are much finer than are those commonly attached and provision made so that the solution can be shut off from either needle. The needle chosen is four inches in length, No. 20. The assistants are impressed with the fact that no pain must be given the patient either during the insertion of the needles or the administration of the solution. To obviate this the skin is bilatered with a few drops of novocaine ($\frac{1}{4}$ per cent solution) using the finest hypodermic needle then a few drops of the same solution is forced along the course we expect the

Fig. 2 Showing application apparatus

needle to follow in the deeper tissue. The point of a fine sharp hypodermoclysis needle is then placed against the skin and gently rotated with firm pressure. This carries the needle in absolutely without pain. After being in place the head is wrapped in gauze so that the flange does not touch the skin and cause pressure and the needle is fixed in position with adhesive plaster. The solution is kept warm by frequently refilling the can or using a sterile hot water bottle in the can. The solution is allowed to drop in slowly never distending the tissue to the point of pain. Whenever the patient says there is a sense of fullness the rubber tube on that side is shut off.

In this manner we have frequently given continuous normal salt solution for three to four days with no disfigurement or ill consequences to the patient. We have used it in children without the slightest complaint on their part. Its use has become a routine in all cases of persistent vomiting and toxæmia as peritonitis, ileus, perniculous vomiting of pregnancy, toxic nephritis, septicæmia, etc. In debilitated patients we have inserted the needles and begun hypodermoclysis at the beginning of an operation and returned the patient to bed with the needles in place and

continued the administration indefinitely. We have used it supplementary to rectal administration of tap water and in those cases where owing to the nature of the operation, e.g., intestinal resection, this could not be used. As an example, Examination of the charts shows that in a seven year old child, Wesley Memorial Hospital No. 56,931 suffering from paralytic ileus 4000 ccm. were given over three days, and in a patient with general peritonitis, Wesley Memorial Hospital No. 57,388 following appendicitis in a young man 9000 ccm. were given over four days. And in another patient, Wesley Memorial Hospital No. 59,154, much dehydrated from persistent vomiting 13000 ccm. were given in 44 hours.

In cases where the heart is growing weak there has been at times a tendency to water logging of the tissue. Therefore such cases are watched carefully so that on the one hand this will not occur and on the other we shall not overload the circulation and strain the heart.

The benefit patients suffering from peritonitis have derived from the combined use of continual gastric lavage and continuous hypodermoclysis is far beyond that secured by any other procedure with which we have had experience.

THE USE OF ELECTRIC LIGHT AND HYPOCHLOROUS ACID IN THE TREATMENT OF WOUNDS

B. GEORGE W. CRILE, M.D., F.A.C.S., LL.D.

CHICAGO

FOR some years the electric light has been utilized in the treatment of burns and in the literature we find occasional mention of the efficiency of electric light treatment for obstinate ulcerating surfaces, such as varicose ulcers, etc. Apparently however the wide applicability of this treatment has not been recognized if one may judge by the paucity of the literature under this heading. Chaput, writing in 1914, states that the wide usefulness of electric light baths was discovered by him during a dark season in which sun baths were unavailable. In many kinds of cases he therefore tried the effect of exposure to the light of a fifteen-candlepower electric lamp applied daily or every other day for hourly periods. As a result of these trials, he found that in the ordinary electric lamp we possess a simple, practical, economical, and very efficient means for treating obstinate ulcers, and infected and gangrenous sores. Chaput predicted also that this conception would find its application in the treatment of certain complications of the wounds of war.

Last year at the American Ambulance in Paris, Dr. Winchester Dubouchet called my attention to the value of electric light in the treatment of infected wounds. Dr. Dubouchet used ordinary

electric lamps, single or in clusters with or without reflectors, the treatment in each case being continued night and day. We gave the method a trial on my service and secured so much better result than by the use of dressings that upon the return of the Lakeside Unit from France we introduced this treatment in Lakeside Hospital and observed its effect upon various types of wounds.

What the experiences of war had proved to military surgeons soon became obvious to us, i. e. that little if any advance in the treatment of infections had been made in many years. We soon realized also that the real reason for the efficiency of the electric light treatment lay in the fact that Nature's own method of promoting repair is thus produced artificially as is demonstrated not only by Chaput's successful substitution of electric light for sun baths, but far more strikingly by the remarkable facility with which wounds heal in desert places. For example in Arizona, where the air is dry and rare and the rays of the sun are direct and strong the carcass of an animal does not readily decompose. In this region, tuberculosis is easily cured and tubercular lesions of the skin and superficial parts heal rapidly.

Fig. The Fuller adjustable bracket for applying electric light treatment to wounds.

Fig. The Bell metal band for electric light

Analysis of sunlight and of ordinary electric light show that they are practically identical. In view of these facts, although we have recognized the therapeutic value of the Finson ray, the Coolidge tube, etc., we have been slow to appreciate that by simply utilizing the radiance and warmth of the ordinary electric lamp, we may bring the dryness, the heat, and the light rays of the desert to the wound to promote its healing.

The omissions of dressings in itself is an important factor in the success of this method. Sir Berkeley Moynihan has stated that the average dressing of a suppurating wound is in effect a pus poultice. Indeed, until I observed the behavior of wounds exposed to the air it had not occurred to me that in dressed wounds the greater part of the discharge was due to the irritation of the dressing.

It is not my purpose here to discuss the theories which may explain the value of heliotherapy, or electric light thermotherapy. These are sufficiently presented in current journals, especially those devoted to electrotherapy and radiology. Nor shall I present the chemical formulae and reactions which indicate the reasons for the efficiency of hypochlorous acid as an antiseptic cleansing agent. These are fully discussed in articles by Dakin and Carrel. My purpose in this paper is to describe the manner in which we are applying electric light treatment and hypochlorous acid in a variety of cases. An apparatus devised by Miss Fuller and Dr. Bell

of the Lakeside Hospital (Figs. 1 and 2) in which electric lamps placed in pasteboard containers or in metal hoods are suspended from an adjustable frame has proved a practical and comfortable means for applying light treatment to wounds of the neck, chest, shoulder, arms or legs. For abdominal wounds, the lights may be suspended from a cradle. The amount of light and the proximity of the lamps to the wounds are governed by the comfort of the patient. For the necessary cleansing of the wounds, we use Dakin's solution¹ or Wright's solution.²

Osteomyelitis. In cases of osteomyelitis a temporary pack is placed over the wound immediately after operation to prevent oozing. After a few hours this is removed and the undressed wound is exposed to several electric light bulbs suspended under a cradle (Fig. 3). The bulbs are near enough to the wound to subject it to comfortable warmth. Secretions from the wound are cleansed with Dakin's solution and if coagulated serum develops, a hot pack with Wright's hypertonic solution applied for half an hour more cleans up the field. In some cases the exposure to the electric light is continued both

night and day. Aside from the hot pack and Dakin's solution, no other dressing or antiseptic is employed. Our experience with the electric light treatment in osteomyelitis has demonstrated three outstanding advantages: the wounds heal more rapidly, much less dead bone appears, the wound discharge is markedly decreased.

Open granulating wounds. That skin grafts do better without dressings is well known, but under exposure to electric light not only cases requiring skin graft but all open granulating surface wounds show increased healing power.

Open tuberculous abscesses. We find that during the first night it is best to pack a tuberculous abscess in order to establish an open wound. After this, these cases do well under hypochlorous acid cleansing, the X-ray being used also while the wound is wide open. We have found that many of these wounds may be sutured within five days, and that fairly good primary healing follows.

Deep drainage. In cases requiring gall-bladder, appendiceal, or pelvic drainage, we find that they progress well under intermittent exposure to electric light and that the patient is much more comfortable under the heat and light.

Cancer of the mouth. After the excision or cauterization of cancer of the mouth, hypo-

chlorous acid is especially useful because it is a deodorant, and not an irritant or a poison.

Empyema. The malodorous properties of empyemata are splendidly controlled by the injection of hypochlorous acid.

Acute infections. In the treatment of acute infections of the joint and of the deeper soft parts, the combination of a continuous irrigation with Dakin's solution through multiple drainage tubes, with exposure to a cluster of electric lights produces excellent results. In severe acute cases the drip irrigation should continue by night as well as by day. Wright's solution also is efficient in these cases.

Aseptic closed wound. We have made a number of observations of the effect of exposure to electric light on aseptic closed wounds and have found that the patient was much more comfortable than with dressing, and that the wound healing was at least as rapid.

CONCLUSION

All living tissue attempts to encyst or to cast off foreign bodies of all kinds. No one would consider the advisability of putting a gauze dressing on a corneal ulcer and yet the violent reaction of the eye to a foreign body differs in degree only—not in kind—from the reaction of living tissue to dressings anywhere. We know that we dare not pack gauze on suture lines, not drain fractures. We know that nails and screws cause the absorption of bone, that any aseptic wound with drainage discharges much fluid, that wounds roughly handled during operations discharge more fluid than clean cut wounds. We know how difficult it is to bury steel plates in bones, to bury heavy silk in aseptic wounds. From the benefits of dressings must be subtracted all the resultant ills—irritation and discharge added, necrosis, pain, and discomfort. Frequently changed hot dressings are more comfortable than plain dressings and perhaps produce less pus, but if applied too long they tend to waterlog the tissue. Moreover the wet hot pack gives no different quality of heat than does the electric light, and the heat from the electric light penetrates quite as readily as the heat from the hot pack.

Wounds heal best when infection is hindered or destroyed by the agent least harmful to the tissue and without the irritation of foreign bodies in the form of dressings. All these ends are served by the use of hypochlorous acid solution and by exposing the undressed wound to constant light and warmth.

THE APPLICATION OF THE SEWING MACHINE STITCH IN GASTRIC AND INTESTINAL ANASTOMOSES

BY E. P. QUAIN, M.D., F.A.C.S., BISMARCK, NORTH DAKOTA

THE illustration presented herewith demonstrate a needle devised by the writer for the purpose of applying a double interlocking suture in gastro-enterostomies and enter-enterostomies. The needle is threaded as shown in Fig. 1 and the other end of the catgut is tightened to a blunt straight needle. The needle is pushed far enough through the two structures about to be sutured serosa-to-serosa fashion so that the eye near the point clears the distal

mucosa by about one fourth inch. The straight needle with the other end of the catgut is now put through the catgut loop near the mucosa as in Fig. 2. The first needle is withdrawn and the stitch pulled tight.

After the suture of the posterior edge of the anastomosis has been completed the stitching is continued back along the anterior margin as shown in Fig. 3.

The two advantages gained over other methods of suture in gastric and intestinal anastomoses are first absolute hemostasis and second saving of time.

Fig. 1

Fig. 2

Fig. 3. Photograph showing anterior half of gastro-jejuno-stomy. The needle is passed into the jejunum out through its serosa and then across the gastric margin which is penetrated in reverse order. The first loop is picked up with the other needle in the gastric mucosa as in Fig. 2. Pulling the two end taut makes firm serosa-to-serosa approximation.

A DETACHABLE APPLIANCE FOR THE CONVERSION OF THE OPERATING CYSTOSCOPE INTO A DOUBLE-CATHETERIZING INSTRUMENT

By P. S. PELOUZE, M.D. PHILADELPHIA

Cystoscope, Urological Department, Jefferson Medical College Hospital

WHEN one tries to pass two ureteral catheters through the Buerger operating cystoscope which is the one most generally used in this country he finds that they stick to each other kink in the channel, and do various other things to promote failure. After a few such experiences, he realizes that the instrument was surely not intended for double catheterizations, and is compelled to resort to the instrument especially designed for such work. A study of these two instruments will show that, as far as the outer sheaths are concerned, there is really no essential difference and as regards the periscopes, the only important difference is that that of the double catheterizing instrument

for which it was made, but it increases the range of intravesical procedures at one passage of the instrument, a point very gratifying to most patients.

One field in which I have found it of particular value is that of separate renal function tests. During such a test the study of the separate urines is of greatest value and it is usually a simple matter to collect them. A number of disappointments in separate efficiency tests has shown me the futility of looking for accuracy in such tests by inserting No. 5 or 6 F catheters into both ureters. The leakage into the bladder during the test period is generally so great as to render the readings useless, as it is impos-

Operating cystoscope with detachable fin by which instrument can be connected with double catheterizing cystoscope

has a fixed fin to divide the unoccupied lumen of the sheath into two separate catheter channels.

Usually the double catheterizing scope is purchased first, the necessity for operating arises, and the physician learns that he must buy an entire new instrument. The similarity in the outer sheaths makes a part of the investment appear unwarranted, but each periscope fits its own particular sheath and there are no universal fits.

To overcome some of these difficulties, I have devised a detachable separating fin which makes it possible to convert in a moment's time, the operating cystoscope into a double catheterizing one that works equally as well as the one made for that purpose. This little appliance is so well illustrated in the accompanying cut that it needs no description.

Not only does it admirably fulfill the purpose

able to state positively from which kidney it came. On the other hand, if one collects his urines for study withdraws the catheters, removes the fin, and inserts the tapering Garceau catheter into one ureter until it entirely fills its lumen and collects the other kidney's urine from the bladder there practically ceases to be a margin of error to consider.

The addition of this appliance to the operating cystoscope, in short, gives one all of the range of usefulness of two models and at a cost very little above the price of a single instrument. While this may not make a strong appeal to the manufacturer, it makes an eloquent one to the physician who starts out to buy an outfit for cystoscopic work. As previously stated, there are no universal fits with these instruments, which fact, unfortunately makes it necessary to fit the attachment to each individual cystoscope.

CONTINUAL STOMACH LAVAGE AND CONTINUOUS HYPODERMICOLYSIS IN PERITONITIS DEHYDRATION FROM VOMITING AND ALLIED CONDITIONS

DR. ALLEN B. KANAVEL presented a paper entitled Continuous Stomach Lavage and Continuous Hypodermoclysis in Peritonitis Dehydration from Vomiting and Allied Conditions (See p 451)

DISCUSSION

DR. DANIEL N. EISENDRATH Dr. Kanavel has presented an excellent idea because there is one factor in acute gastric dilatation (post-operative) that we are apt to overlook and which this tube will help greatly in removing. Everyone has probably noticed in cases of acute dilatation that after you have washed out the stomach and have not given the patient a drop of water by mouth, inside of three or four hours there will be an accumulation of more or less fluid again. It took me quite a while to understand that this is due to hypersecretion from the gastric mucosa. There is very little or nothing said about this condition in the literature. It is a sort of gastrosuccorhoea. It seems to me a tube which is kept constantly in the stomach will help greatly because, after the preliminary washing out a suction tube will take care of the disagreeable hypersecretion.

There is one thing in this connection I would like to call attention to which we have observed recently and have tried to control as much as possible, and that is the determination of the amount of carbon dioxide. Dr. Wright is working out the relation between acidosis and gastric dilatation. Many of these cases are instances of acidosis and the

moment when an introl that has gradually increased our introl with a tube gastric dilatation

THE USE OF NAIL EXTENSION IN FRACTURES

DR. F. C. DAY presented a paper on The Use of Nail Extension in Fractures (See p 458) which was illustrated by numerous slides

DISCUSSION

DR. KEEL W. SPEED I would like to say a few words on this method because I have been using it for two or three years.

First of all the copper wire loop has a long history and I may as well tell it to you. In the first case in which I used this method I asked an interne to get a wire loop and put it on the nail. He was not able to get it. I told him to get a steel rod but he found copper wire which I had used before. I told him it worked so well that I adopted it in subsequent cases. For the nail I have been using a steel drill rod five sixths of an inch in diameter cut off at the required length. The traction on the nail can be relieved if the patient is distressed by moving it and replacing it. The nail also controls the amount of rotation to either side in fractures of the femur when applied to the femur itself. The nail becomes loose in the os calcis in about 15 or 20 days.

We have had two cases of accident in connection with the nail in the hole. In one on the third week the patient getting tired of the traction reached down and pulled the nail out but the interne discovered this quickly and by injecting a small amount of iodine in the hole through the bone we avoided any infection.

The second case was brought to the operating room for the removal of a nail as it had become loose. In fractures of the femur of which I have had but few cases, I have found the nail is not loose in three weeks. I use a much larger nail through the femur in such cases.

I have had one case with a result after three weeks by traction from the femur seemingly as good as that shown. The leg was put in a cast after that time and the fragments slipped back because the callus was not hard enough. In subsequent cases we found the results were better when treated for five weeks with a nail through the femur.

In the pictures Dr. Dyas has shown us in one case I am sure that the nail was not put through the os calcis. That does not make any difference, because if the nail is pulled very hard it may pull through the os calcis and impinge on the heavy plantar fascia and plantar tissues which will hold just as well as bone will. This method has been tried by putting a nail *not* through the bone itself, but in the space in the tendo Achillis and in the space in the os calcis and it works just as well.

The apparatus Dr. Dyas has shown you for foot drop it seems to me, is entirely unnecessary because when the extension is applied to the os calcis there is absolutely no tendency for the anterior portion of the foot to drop down. At least, I have never seen it. The os calcis itself, on account of its cancellous structure, lacerates under this type of treatment, and the nail is easily inserted.

I want to say a word about the intensity of the traction in the knee and ankle. The separation that was apparent in some of these cases is due to the stretching of the joint ligaments. That is not of a permanent character because after the traction is relieved the joint resumes its normal condition and there is no permanent damage done of which I know.

The results are not distinctly anatomical. I have never obtained a satisfactory X-ray picture of a case that showed anatomical reduction, but functionally the legs are brought into weight-bearing line and are very satisfactory.

Dr. WILLIAM FULLER. I think that almost any method of treating fractures will answer the purpose sometimes. However if we discuss methods their value cannot be correctly estimated unless we at the same time specify the particular kind of fracture in which we would employ a particular method.

While the Lane bone plate has fallen into disfavor owing almost entirely to its misunderstood principles and its indiscriminate use by those who should know better, as well as by those who do not, I still believe that this device has a very distinct and an important place in the treatment of fractures.

Instead of the intelligent application of many other measures now at our disposal in fracture work they are entirely misunderstood and are made use of under conditions which are often without the slightest justification. Strenuous efforts at traction and extension are often made where such are not needed, just as they are of least and the least consideration when they are needed.

As one writer has said we individualize too little in our treatment of fractures. No measure yet described is without some value somewhere, but in order to decide just what procedure should be followed, a careful diagnosis should always be made and every indication accurately determined. Then if we select the particular measure or part thereof which is rightly called for and display intelligence and understanding in the use of whatever that may be the end-results should be satisfactory.

The nail driven into bone for the purpose of traction, as described by Dr. Dyas tonight and by others before this, may have place in the treatment of fractures. But of all the maneuvers yet described I should not hesitate to give this one the last place especially when used as a means of affording traction. It necessarily offers some difficulties in placing it exactly in the bone as desired. It is in reality an open operation. It is liable not to hold when great traction is made upon it. It establishes a communication between an open skin at one end of the nail, and a bone lesion surrounded by damaged soft parts at the other end and what is of more importance than all other points combined is the use we can make of older and well-tried methods which call for no operative work and which hold just as well perhaps better. But notwithstanding these objections, Dr. Dyas has shown that the nail can be used advantageously. The nail for purposes of extension, the Lane plate, the bone plug, the transplant, the screws, the wire, all have some merit and can when judiciously employed be of service.

Surgeons have long hoped for a more rational means of treating fractures. That time will probably not come till the general medical man ceases altogether his efforts in this work, and when the general surgeon devotes more time and thought to it and exercises the same care and consideration as he ordinarily employs elsewhere.

There are more malpractice suits brought against members of the profession for their failures to satisfy the public in the treatment of fractures than in all other work combined. Why is this? It is because other surgical work is not done as blindly carelessly and unscientifically as is the treatment of fractures. In surgery of the head of the thorax, and the abdomen, ample room, good exposure and abundant light are demanded. The end results in the treatment of fractures will be no less so when we treat fractures on the same rational basis as is the rule in surgery in other parts of the body.

We cannot all agree with Dr. Dyas when he says that the nail sticking from the skin surface as he has shown here is as little likely to produce an infection as the open operation. The nail hole is virtually a drain track and we are familiar with some of the dangers attending these when located near clean wounds. Just how they can be less serious when made by a nail transfixing the broken limb and passing out to the surface to be occasionally toyed with as happened in one of Dr. Dyas' cases, is not clear.

In closing I would say that no device or measure should ever be used in the treatment of any fracture simply because it is new but only when they have shown unmistakably that no other device or method can serve the purpose as well.

Dr. DANIEL N. EISENDRATH. I would take exception to Dr. Dyas' condemnation of the lack of value of Buck's extension. If properly applied, Buck's extension is of the greatest value. It can

DR. C. G. BURTON: My experience with fractures has not been small. From the hysteria that has developed on the account of so-called improved methods in the treatment of fractures it might seem to those outside of surgical circles that fractures have been giving us a great amount of trouble and that we have been laden with damage suits. Such has not been my experience or my observation.

My methods have pretty generally been along the old plans of treatment, namely: attempt at simple reduction under anesthesia when necessary and the use of Buck's extension in the extremities when indicated. Simple fixation appliances have been used early and open or closed casts used as permanent dressings. I think I get as good results as can be obtained. I have no cripples running around, no complaints from the patients, and have never had

damage suits threatened connected with fractures. I rarely use the Lane plate or bone peg. When reductions are impossible and deformities are objectionable I usually do an open operation and approximate the fragments closing without drainage. Once the fragments are in position it is easy to hold them there. It is the fragments that are not in position which make it difficult to retain them in their proper position. I do want it understood that the Lane plate and bone peg, like other good devices, have their places in surgery but since their introduction I believe as most of you here believe that they invite too many operations and are used entirely too frequently. I have been amazed at the large number of plates and pegs reported from the services of men with relatively small amount of work. I feel that the nail brought out by Dr. Dyas is a good thing in its place. It will certainly have its field of usefulness. I have personally never had occasion to use it.

The special note which I desire to sound is: Do open operations if you must but leave fewer and fewer foreign materials in the wound.

DR. DYAS (closing): I want to give Dr. Speed full credit for introducing this method in the treatment of fractures at the Cook County Hospital. He was the first man to use it and with his permission I will say that when I began this work we endeavored to get a group of cases together which would enable us to make a report of some value by reason of the number of cases treated. He deserves full credit for the detailed technique which we have carried out in our work.

I knew my paper would be criticized but if surgeons are absolutely satisfied with the way they are going along in treating fractures and try nothing new they will never make any progress. I feel that our results have justified the work. It is our intention to treat further cases with this method so that we may obtain reliable information. We have not done any injury to any patient. We have not had infection in a single case. We have not had absolutely accurate anatomical results but we have had good functional results.

As to Buck's extension, I did not mean to condemn it to the extent that some of the speakers do but it is perfectly true from a mechanical standpoint that it is impossible for any one to expect to apply as much traction by means of adhesive plaster to the skin as can be applied by definite exact traction apparatus, such as the nail and copper wire and pulley extension. Buck's extension has a wide field of usefulness and always will have. The method I have described is not intended to supplant anything but it has its place with strict indications and I think the functional results will justify the use of the method.

THE CLINICAL CONGRESS IN PHILADELPHIA

BY EDWARD MARTIN, M.D., F.A.C.S.

THE clinical meetings of the surgeons of North America have been characterized by an attendance which in many cases seriously threatened the security of the part of individual members of those bodies which they so willingly and in such great numbers sacrifice time of convenience, business and money to attend. There seems any escape from a species of universal manipulation other than by limiting the number attending to accord with the facilities for observation offered and by adopting a system founded on experience which assures each visitor his seat or place in the day.

This meeting for the second time in Philadelphia, is notable from a number of circumstances from that of the character of the men attending it—the urgent business of the country—each an influence in his own community—many with hospitals of their own, practically all operating surgeons who come serious-minded to better their work. None will go home feeling that they have so done some

with the profession in which they are engaged and in the knowledge that they have done so.

From these facts it is not surprising that the attendance has been so large. The attendance of the surgeons of North America at the Philadelphia meeting was the largest ever recorded. The attendance of the surgeons of North America at the Philadelphia meeting was the largest ever recorded. The attendance of the surgeons of North America at the Philadelphia meeting was the largest ever recorded.

In accordance with the practice which obtained at Boston and in accordance with the efforts which the Congress has done in the last better clinical records and following case their comparison, there will be a report of results to date. All operative cases before the visiting surgeons this morning.

presented at the next annual meeting of the Congress. This at times gives a better opportunity of estimating the true capacity of a surgeon than does a mere observation of his operative technique. Indeed it is the one criterion of a surgeon's ability and usefulness. Moreover the knowledge that such a report is required may in some instances induce a wholesome conservatism on the part of the operator which is in the main largely to the interest of the patient.

Incidentally Philadelphia has many excellent hotels a medical library at the College of Phys-

cians, second in completeness only to that of the Surgeon-General's and in its environs, within twelve miles of the center of the city more than a dozen golf links the latter readily made available to those who have inclination and time for the game during these busy meetings. It is scarcely needful to say that a cordial welcome awaits the guests from the Philadelphia profession who feel honored by the choice made of them stimulated by the hopes bound in them and will remain permanently bettered by association with the broad men from all parts of this broad country.

PLANS FOR THE PHILADELPHIA MEETING

On the morning of Monday October 23 in Philadelphia the Clinical Congress of Surgeons of North America opens its seventh annual session. The Congress headquarters at the Bellevue-Stratford will be open for the registration of members on the afternoons of Saturday and Sunday preceding and the program for Monday's clinics and demonstrations will be posted on Saturday afternoon.

The Philadelphia Committee on Arrangements, backed by the clinicians of that city are keenly interested to make a complete showing of Philadelphia's clinical facilities in every department of surgery including gynecology obstetrics genito-urinary surgery orthopedics, surgery of the eye ear nose, and throat. While the chief attraction will be the clinics in the operating rooms of the thirty or more co-operating hospitals, a series of demonstrations—pathological roentgenological borderline subjects, and others—has been arranged by the committee and it is expected that this portion of the program will prove of exceeding interest.

The clinical program appearing on the following pages is only suggestive of what the Philadelphia clinicians have in mind for the week of the Congress. The daily program as bulletined at headquarters will be elaborate and accurate in detail as to the cases to be operated upon or demonstrated in the several clinics.

These annual clinical meetings have become so popular that the plan of limiting the attendance and requiring advance registration was decided upon to prevent overcrowding. Such a plan has proven successful at the two previous meetings, as it insures accommodations at the

clinics for all who hold membership cards. It is evident at this time from the number of registrations already received at the office of the Secretary-General that the limit of membership for the Philadelphia meeting will be reached some time in advance of the meeting. The limit was fixed after making a careful survey of the operating amphitheatres, lecture rooms and laboratories of the several medical schools and hospitals as to their capacity for accommodating the visiting surgeons.

EVENING MEETING

On Monday evening at 8 o'clock in the ball room of the Bellevue-Stratford occurs the presidential meeting at which time the officers elected at the Boston meeting will be inaugurated. The presidential address will be delivered by Dr. Fred B. Lund of Boston the president elect. On each of the three following evenings there will be sessions of the section on general surgery in the ball room of the Bellevue-Stratford and on the same evenings separate meetings for the section on surgery of the eye ear nose and throat in another room in the same hotel. The program for these evening meetings appears on the following pages. These meetings open promptly at 8 o'clock and adjourn not later than 10.30.

On Friday evening in Witherspoon Hall at 8 o'clock there will be held a public meeting under the combined auspices of the Clinical Congress of Surgeons, the Philadelphia County Medical Society and the Department of Public Health and Charities of Philadelphia to which meeting the public at large is invited.

HEADQUARTERS

The Congress will utilize for its headquarters at the Bellevue Stratford the Ball Room, Clover Room, Red Room, Green Room and adjacent foyers and smaller rooms on the second floor of the hotel providing ample space for registration and ticket bureaus, bulletin board, etc., the ball room being used for the evening sessions.

The program of clinics and demonstrations for Monday will be bulletined on Saturday afternoon, and on each afternoon beginning on Monday the complete program for the next day's clinics will be posted on bulletin boards in headquarters. A printed program will be issued each morning.

SPECIAL TICKETS

Attendance at all clinics and demonstrations will be controlled by means of special tickets. The general rule will be that a member may have two tickets for each day, one for the morning and one for the afternoon clinics. For certain clinics where the accommodations are limited and the demand for tickets is heavy, it will be necessary to establish a rule whereby a member may have only one ticket for such clinic during the week. The number of tickets issued for any clinic or demonstration is limited to the capacity of the room in which the clinic or demonstration is to be given.

The use of special tickets has proven an efficient means of providing for the distribution of members among the several clinics and insures against overcrowding at any clinic. Special tickets will be issued each morning at 8 o'clock for the clinics and demonstrations to be held that day, a complete schedule of the day's clinics having been posted on the bulletin board on the afternoon of the preceding day, and a printed program distributed in the morning.

REDUCED RAILWAY FARES

The railways in the states east of the Mississippi River excepting the southeastern states south of the Ohio and Potomac Rivers and in the eastern portion of Canada have granted certain reductions in fares in selling round trip tickets to Philadelphia on account of the Clinical Congress of Surgeons. Round trip tickets will be sold at the rate of two cents per mile in each direction going and returning by the same route only and over which one way tickets are regularly sold. Tickets will be on sale from points within the territory specified on October 21st

22nd and 23rd with a general return limit to reach one's original starting point on or before midnight November 1st.

In particular these reduced rates will be in effect in the territory covered by the railway lines in the New England Passenger Association, Trunk Line Association, Central Passenger Association and Eastern Canadian Passenger Association. An application for the granting of the same reduction in fares by the lines in the southeastern states is now pending and probably will be acted upon favorably.

Members living in the states west of the Mississippi River and within the territory covered by the Western and Southwestern Passenger Association—that is west of Chicago and St. Louis—should purchase tickets to those gateway cities and then repurchase round-trip tickets to Philadelphia in order to avail themselves of the reduced fares.

The Baltimore and Ohio Railroad is prepared to offer members of the Congress from Chicago and the West attending the Philadelphia meeting special service on train leaving Chicago at 5:45 p.m. Saturday, October 1st, arriving Philadelphia at 5:10 Sunday evening and on train leaving Chicago at 10:45 Sunday morning arriving Philadelphia at 1 p.m. Monday. The Michigan Central Railroad in connection with the Lehigh Valley and the Philadelphia and Reading offers special service on its train leaving Chicago at 3:05 Sunday morning arriving Philadelphia at 9:15 Monday morning. From the Northwest the Great Northern Railway is making special arrangement for the benefit of members living along its lines while from the Southwest the Atchafalpa, Topeka and Santa Fe will likewise offer special facilities.

MEMBERSHIP—REGISTRATION FEE

The Constitution of the Congress provides that all subscribers to the official journal *SURGICAL Gynecology and Obstetrics* are members of the Congress and that such other legally qualified practitioners as are in good standing in their own communities may become members upon registering at an annual meeting. A registration fee is required of each member attending an annual meeting, there being no annual dues for members of the Congress. The registration fees provide funds to meet the expense of preparing for and conducting the annual meetings so that no financial burden is imposed upon members of the profession in the city entertaining the Congress.

PRELIMINARY CLINICAL PROGRAM

GENERAL SURGERY

Monday

CHARLES H. FRANKER — University Hospital — 0 to 1
 T. TURNER THOMAS — University Hospital — 3 to 4
 GEORGE G. ROSS — German Hospital — 0
 A. D. WHITTON — German Hospital — 10
 JOHN B. DEAYER — German Hospital — 10
 E. G. ALEXANDER — Episcopal Hospital — 10
 HARVEY C. DEAYER — Episcopal Hospital — 1 to 4
 W. WAYNE BARCOCK — Samaritan Hospital — 0 to 2
 NATHANIEL GREENBERG — Jewish Hospital — 0 to 1
 M. BEHREND — Jewish Hospital — 2 to 3
 KATH W. BALDWIN — Women's Hospital — 3
 LEVI J. HANCOCK — Methodist Episcopal Hospital — 10
 W. O. HEDMANN — Polyclinic Hospital — 10
 MORRIS BOOTH MILLER — Polyclinic Hospital — 10
 LEWIS H. ADLER — Polyclinic Hospital — 10
 JOHN B. ROBERTS — Polyclinic Hospital — 4 to 5
 FRANCIS T. STEWART — Jefferson Hospital — 4
 MELVIN M. FRANKLIN — St. Joseph's Hospital — 10 to 3
 W. HENRIK THOMAS — Medico-Chirurgical Hospital — 0 to 2
 JOHN A. BOONE — St. Mary's Hospital — 10

Tuesday

H. R. OWEN — Philadelphia General Hospital — 10
 H. R. LOUK — Philadelphia General Hospital — 10 to 4
 J. B. CARRETT — University Hospital — 0 to 10
 A. C. WOOD — University Hospital — 10 to 2
 W. WAYNE BARCOCK — Samaritan Hospital — 0 to 10
 LEON BRIDEMAN — Mt. Sinai Hospital — 10 to 2
 A. P. C. ARNHEIM — Episcopal Hospital — 0 to 10
 L. H. MULLER — Episcopal Hospital — 0 to 4
 NATHANIEL GREENBERG — Jewish Hospital — 0 to 10
 WILLIAM H. TELLER — Jewish Hospital — 0 to 5
 J. M. BALDWIN — Methodist Episcopal Hospital — 10 to 4
 SAMUEL McCLEARY III — Oncologic Hospital — 10 to 4
 CHARLES H. FRANKER — University Hospital — 0 to 1
 G. P. MUELLER — University Hospital — 1
 NATHANIEL GREENBERG — Jewish Hospital — 0 to 1
 WILLIAM H. TELLER — Jewish Hospital — 1 to 5
 W. B. VAN LEEUW — Hahnemann Hospital — 10
 JOHN SPEER — Polyclinic Hospital — 0 to 10
 JOHN H. GIBSON — Polyclinic Hospital — 1 to 1
 JOHN H. GIBSON — Jefferson Hospital — 10
 JAMES A. KELLY — St. Joseph's Hospital — 10 to 3
 J. T. C. JONES — St. Joseph's Hospital — 3 to 5
 A. C. WOOD — Howard Hospital — 10 to 30
 E. L. ELIASON — Howard Hospital — 10 to 30
 EMMET LAPLACE — Medico-Chirurgical Hospital — 0 to 1

JOSEPH H. ROSS — St. Mary's Hospital — 1
 D. ROMAN — St. Luke's Hospital — 10 to 5
 LEON BRIDEMAN — St. Agnes Hospital — 1 to 4
 GEORGE M. DOORANCE — St. Agnes Hospital — 0 to 1

Wednesday

EDWARD MARTIN — University Hospital — 0 to 10
 E. L. ELIASON — University Hospital — 1 to 10
 W. P. HEARN — Philadelphia General Hospital — 0
 CHARLES HANSON — Mt. Sinai Hospital — 1
 A. P. C. ARNHEIM — Episcopal Hospital — 0 to 10
 NATHANIEL GREENBERG — Jewish Hospital — 0 to 1
 M. BEHREND — Jewish Hospital — 1 to 3

W. B. VAN LEEUW and H. L. NORTROP — Hahnemann Hospital — 30
 FRANCIS SPRACUE — Woman's Hospital — 3
 LEVI J. HANCOCK — Methodist Episcopal Hospital — 10
 WILLIAM A. STEEL — Samaritan Hospital — 0 to 1
 JOHN A. BOONE — St. Joseph's Hospital — 0
 JOHN B. DEAYER — German Hospital — 1
 GEORGE P. MUELLER — Polyclinic Hospital — 10
 J. CHARLES DA COSTA — Jefferson Hospital — 10
 CHARLES F. NARRAU — St. Joseph's Hospital — 1 to 10

MELVIN M. FRANKLIN — St. Joseph's Hospital — 1
 EMMET LAPLACE — Medico-Chirurgical Hospital — 0 to 10
 ELLWOOD R. KIRK — St. Mary's Hospital — 1
 WILLIAM J. T. LOK — St. Agnes Hospital — 1 to 4

Thursday

Days to be Observed

C. R. F. W. OUTERBRIDGE—Medico-Chirurgical and Philadelphia
 L. L. CHARIT—Hospital—

ORTHOPEDIC SURGERY

Monday

- J T ROSS and staff — Methodist Episcopal Hospital — 4 to 5
 A. B. GILL — Episcopal Hospital — t 5
 JOSEPH M. SPILLER — St. Joseph Hospital — 3 to 4

Tuesday

- M. M. FRANKLIN — Philadelphia General Hospital — to 4
 J T ROSS and staff — Methodist Episcopal Hospital — 4 to 5
 H. A. WILSON and staff — Jefferson Hospital —
 W. J. TAYLOR and staff — Orthopedic Hospital — to
 J. P. MANN — Medico-Chirurgical Hospital — to 3.
 HARRY HUDSON and staff — Samaritan Hospital — t 4
 G. G. DAVIS and staff — University Hospital — to 3.

Wednesday

- G. G. DAVIS and staff — University Hospital — to 4
 J T ROSS and staff — Methodist Episcopal Hospital — 4 to 5
 A. B. GILL — Episcopal Hospital — 9 to
 JOSEPH M. SPILLER — St. Joseph Hospital — t 4.

Thursday

- H. A. WILSON and staff — Jefferson Hospital —
 G. C. DAVIS and staff — Orthopedic Hospital — to
 J. P. MANN — Medico-Chirurgical Hospital — to 3
 J. K. YOUNG and staff — Polyclinic Hospital — t 3
 G. C. DAVIS and staff — University Hospital — t 3

Friday

- J T ROSS and staff — Methodist Episcopal Hospital — 4 to 5
 G. C. DAVIS — Widener School — t 4
 G. C. DAVIS and staff — University Hospital — t 3
 J. K. YOUNG — Philadelphia General Hospital — to 4
 J T ROSS — Philadelphia General Hospital — t
 DR. J. MOORE — Hahnemann Hospital —
 JOSEPH M. SPILLER — St. Joseph Hospital — t 4.

Saturday

- A. P. C. VANDERBURG and staff — Orthopedic Hospital — 9 to
 H. A. WILSON and staff — Jefferson Hospital —

GENTTO-URINARY SURGERY

Monday

- H. R. LOUX and staff — Jefferson Hospital — to
 A. A. UZZE and Wm. H. BLACKBURN — German Hospital — 4 to 5

Tuesday

- E. H. SITER — Philadelphia Hospital — to 3.
 B. A. THOMAS — Polyclinic Hospital — t 3
 H. R. LOUX and staff — Jefferson Hospital — to

Wednesday

- H. M. CHRISTIAN — Medico-Chirurgical Hospital — t to t
 E. H. SITER and staff — University Hospital — t
 ELWOOD KIRBY — St. Mary's Hospital — to
 H. R. LOUX and staff — Jefferson Hospital — to

Thursday

- L. T. ABERCRAFT — Hahnemann Hospital — t
 L. T. ABERCRAFT — Women's Homeopathic Hospital — t 3
 H. R. LOUX — Jefferson Hospital — 9 to
 T. R. NEUMAN — University Hospital — t
 EDWARD M. WIT — University Hospital — 9 to 10.
 E. H. SITER and staff — University Hospital — t
 CHARLES HENCH — University Hospital — t 3

Friday

- L. T. ABERCRAFT — Women's Homeopathic Hospital — t 3
 B. A. THOMAS — Polyclinic Hospital — 2 to 3
 H. R. LOUX and staff — Jefferson Hospital — t
 A. A. UZZE and Wm. H. BLACKBURN — German Hospital — 4 to 5

ROENTGENOLOGY

Monday

- SIMON FELDSTEIN — Jewish Hospital — 9 to 10. Oblique and interesting fractures.
 A. G. MILLER — German Hospital — to
 GEORGE E. FRANK — Medico-Chirurgical Hospital — 30 to 3.30. Roentgen therapy in the treatment of deep-seated malignant disease.
 W. S. NEWCOMB — Presbyterian Hospital — to 3. Bone lesions. Sinus cases (in conjunction with Dr. Stauffer)

Tuesday

- DAVID R. BOWEN — Pennsylvania Hospital — to Fractures.
 FREDERICK C. HUTTON — 1438 N. 5th St — to Organic lesions of the stomach and duodenum.
 W. F. ALABRICK — Jefferson Hospital — t 3. Pyelocopy and pyelography.
 W. S. NEWCOMB — Presbyterian Hospital — to 3. Bone lesions. Sinus cases (in conjunction with Dr. Stauffer)

- A. G. MILLER — German Hospital — t
 GEORGE E. FRANK — Medico-Chirurgical Hospital — 30 and 3.30. Roentgen diagnosis of gastric and duodenal lesions. Lantern slide demonstration.

Wednesday

- W. F. ALABRICK — Jefferson Hospital — to 3. Fluorocopy of the gastro-intestinal tract.
 A. G. MILLER — German Hospital — t
 W. S. NEWCOMB — Presbyterian Hospital — t 3. Bone lesions. Sinus cases (in conjunction with Dr. Stauffer)
 GEORGE E. FRANK — Medico-Chirurgical Hospital — 30 to 3.30. Roentgen diagnosis of gall-stones.
 DAVID R. BOWEN — Pennsylvania Hospital — t Bone and joint diseases.
 M. K. FRANK — Stetson Hospital — Joint diseases and radiography of the urinary tract.
 JACOB W. FRANK — Hahnemann Hospital — 9

WILLIAM CAMPBELL POSEY — Wills Eye Hospital —
 P. N. K. SCHWENK — Wills Eye Hospital — 30.
 WILLIAM ZENTMAYER — Wills Eye Hospital — 2.
 MARY BOCHAMAN — Woman Hospital — 2.
 G. ORAM RING — Episcopal Hospital — 2.
 WENDELL REBER — Samaritan Hospital — 4 & 5.
 AARON BRAY — Lebanon Hospital —
 H. T. HANSELL — Philadelphia General Hospital —
 to 3.
 M. CLUKEY RADCLIFFE and J. M. GRISCOM — Presby-
 terian Hospital — 2.
 C. P. FRANKLIN — Stetson Hospital —
 G. E. DE SCHWENITZ and J. T. CARPENTER — University
 Hospital — 3.
 G. E. DE SCHWENITZ — University Hospital — 5.
 JOHN A. BROPHY — St. Agnes' Hospital — 1 to 4

Wednesday

WILLIAM T. SNOOKMAKER — German Hospital —
 CHARLES W. LEEVER and S. J. GITTLESON — Mt. Sinai
 Hospital — 3.
 L. WERTER FOX — Medico-Chirurgical Hospital —
 S. LEWIS ZIEGLER — Wills Eye Hospital —
 SAMUEL D. RUBLEY — Wills Eye Hospital — 2.
 M. CLUKEY RADCLIFFE — Wills Eye Hospital — 3.
 WILLIAM M. SWEET — Wills Eye Hospital —
 P. UL. PONTUS — Wills Eye Hospital —
 WENDELL REBER — Polyclinic Hospital — 1.
 WILLIAM ZENTMAYER — Polyclinic Hospital — 4.
 WILLIAM T. SNOOKMAKER — German Hospital —
 CHARLES J. JONES — St. Joseph's Hospital — 3.
 MIRIAM M. BUTT — Woman's Hospital — 2.
 H. G. GOLDENRO — Episcopal Hospital — 2.
 LOUIS LOVE — St. Mary's Hospital — 4.
 J. C. KNIPS — Jewish Hospital —
 JOHN W. CROOKY — Philadelphia General Hospital —
 to 5.
 EDWARD A. SWEETWAY — Philadelphia General Hospital —
 3 to 4.
 T. B. HOLLOWAY and H. M. LANGDON and CARL WILLIAMS
 — University Hospital — 5.

SURGERY OF THE EAR, NOSE AND THROAT

Monday

CHARLES P. GRAYSON — University Hospital —
 R. SKILLERN — Medico-Chirurgical Hospital —
 I. JONES — Philadelphia General Hospital — 2.
 MARGARET BUTLER — Woman Hospital —
 CURTIS EVER — Episcopal Hospital — 2.
 CARLE LEE FELT — Stetson Hospital —
 RALPH BUTLER — Polyclinic Hospital — 3 to 5

Tuesday

F. R. PACKARD — Pennsylvania Hospital — 2.
 D. B. KYLE — Jefferson Hospital — 2.
 RALPH BUTLER and JAMES A. BARNETT — German Hos-
 pital — 30.
 I. G. SHALLGROSS and H. S. WEAVER — Hahnemann
 Hospital — 30.
 R. SKILLERN — Medico-Chirurgical Hospital —
 FRED W. SMITH and OSCAR SEELEY — Hahnemann Hos-
 pital — 30.
 CHARLES C. BIDGENT — Episcopal Hospital —
 LAURA E. HUNT — Woman's Hospital —
 WALTER ROBERTS — Methodist Episcopal Hospital
 — 3.
 HUDSON MAADEN — Polyclinic Hospital —

Thursday

PHILIP H. MOORE — Methodist Episcopal Hospital — 4.
 JOHN A. BROPHY — St. Agnes' Hospital — 4.
 J. C. KNIPS — Jefferson Hospital — 3.
 WILLIAM T. SNOOKMAKER — Pennsylvania Hospital —
 GEORGE S. CRAMPTON — Pennsylvania Hospital — 2.
 WILLIAM CAMPBELL POSEY — Wills Eye Hospital — 2.
 P. N. K. SCHWENK — Wills Eye Hospital — 1 to 30.
 C. P. FRANKLIN — Stetson Hospital —
 WILLIAM ZENTMAYER — Wills Eye Hospital —
 MARY BOCHAMAN — Woman Hospital —
 FREDERICK KRAUSE — Episcopal Hospital — 2.
 AARON BRAY — Lebanon Hospital — 2.
 JAMES THORNTON and J. M. GRISCOM — Presbyterian
 Hospital — 2.
 G. E. DE SCHWENITZ and E. A. SWEET — University
 Hospital — 3.
 H. T. HANSELL — Philadelphia General Hospital — 1 to 3

Friday

H. T. HANSELL and WILLIAM M. SWEET — Jefferson
 Hospital — 45.
 S. LEWIS ZIEGLER — Wills Eye Hospital —
 SAMUEL D. RUBLEY — Wills Eye Hospital — 2.
 M. CLUKEY RADCLIFFE — Wills Eye Hospital — 3.
 P. UL. PONTUS — Wills Eye Hospital —
 E. A. SWEET and H. M. LANGDON — Children Hos-
 pital — 2.
 WENDELL REBER — Polyclinic Hospital —
 WILLIAM T. SNOOKMAKER — German Hospital —
 CHARLES J. JONES — St. Joseph's Hospital — 3.
 LOUIS LOVE — St. Mary's Hospital — 4.

Saturday

WILLIAM T. SNOOKMAKER — Pennsylvania Hospital — 2.
 GEORGE S. CRAMPTON — Pennsylvania Hospital —
 P. N. K. SCHWENK — Wills Eye Hospital — 30.
 WILLIAM ZENTMAYER — Wills Eye Hospital —
 AARON BRAY — Lebanon Hospital —
 WILLIAM CAMPBELL POSEY — Wills Eye Hospital —
 WILLIAM ZENTMAYER — Polyclinic Hospital — 3 to 4

LOUIS J. BUTLER and WILLIAM P. GRADY — St. Mary's
 Hospital — 3 to 5.
 BENJAMIN D. PARKER — St. Agnes' Hospital — 1 to 4

Wednesday

WALTER ROBERTS — Polyclinic Hospital —
 R. SKILLERN — Medico-Chirurgical Hospital —
 CARLE LEE FELT — Stetson Hospital —
 I. G. SHALLGROSS and H. S. WEAVER — Hahnemann
 Hospital — 2 to 30.
 FRED W. SMITH and OSCAR SEELEY — Hahnemann Hos-
 pital — 30.
 CURTIS EVER — Episcopal Hospital — 3.
 HENRY C. ORF — Oncologic Hospital — 2.
 D. BRADEN KYLE — Jefferson Hospital — 2.
 GEORGE M. MARSHALL — St. Joseph's Hospital — 2
 to
 MARGARET BUTLER — Woman Medical College Hospital —
 J. LEMUE D. VAN — St. Agnes' Hospital — 1 to 4

Thursday

I. G. SHALLGROSS and H. S. WEAVER — Hahnemann
 Hospital — 30.

FRED W. SMITH and OSCAR SEELEY — Halleman Hospital — 230
 CHARLES C. BIRD ET — Episcopal Hospital —
 WALTER FOSTERS — Methodist Episcopal Hospital —
 LAURA HUNT — Woman's Medical College Hospital —
 LOUIS J. BURNS and WILLIAM P. GRAY — M. —
 Hospital — 3 to 6
 D. BRADEN KYLE — Jefferson Hospital — 1
 A. W. WARE — Philadelphia Hospital — 1 to 2
 BENJAMIN D. PARRISH — Allen Hospital —

FRIDAY

SETH MACCUTEN SMITH — Jefferson Hospital — 1 to 2
 GEORGE M. COATES — Pennsylvania Hospital — 1
 I. G. SHALLOCKROSS and H. S. WEAVER — Halleman Hospital — 30

FRED W. SMITH and OSCAR SEELEY — Halleman Hospital —
 GLASCO J. PALMER — Halleman Hospital —
 CHARLES C. BIRD ET — Episcopal Hospital —
 MAX ARIST WARE — Woman's Medical College Hospital —
 I. G. SHALLOCKROSS and H. S. WEAVER — Halleman Hospital —
 D. BRADEN KYLE — Jefferson Hospital —
 A. W. WARE — Philadelphia Hospital —
 BENJAMIN D. PARRISH — Allen Hospital —

ALEXANDER RADFORD — University Hospital —
 CHARLES P. GARDNER — Memorial Hospital —

PRELIMINARY PROGRAM OF EVENING SESSIONS

GENERAL SURGICAL DIVISION — In the Ball Room of the Blue Tree Hotel

Presiding Officer: M. C.

Address of Welcome: ROBERT G. LECONTE, M.D., Philadelphia, Chairman, Committee on Arrangements
 CHARLES H. MAYO, M.D., Rochester, Minn., Address of Welcome, President
 Inauguration of President FRED BATES LUND, M.D., Boston, Vice-President J. P. R. HALL, M.D.,
 Winnipeg, and M. D. CLARK, M.D., New Orleans
 Presidential address by FRED BATES LUND, M.D., Boston, The Indications of Cholecystectomy

CASE 14. No. 3 7709 Age 27 M. Erection of pus epigastric pain loss of weight, fainting spells. Pre-operative diagnosis duodenal ulcer. Operation, Oct. 26 either Dr F B Lund. Stomach and gall-bladder normal appendi infected and adherent. Appendectomy. Post-operative diagnosis, chronic appendicitis. Complications, none. Discharged Nov 8 wound healed.

CASE 5. No. 3 7037 Age 76 F Lump in left breast. Pre-operative diagnosis, carcinoma of breast. Operation, Oct. 26 either, Dr F B Lund amputation of breast dissection of axilla. Post-operative diagnosis same metastasis in lymph-nodes. Complications, none. Discharged Nov 9 wound healed.

CASE 6. N 3278 5. Age 26 F Tumor of abdomen. Pre-operative diagnosis, ovarian cyst. Operation, Oct. 6 either Dr F B Lund, removal of ovarian cyst. Post-operative diagnosis same. Complications, none. Discharged Nov condition excellent wound healed. Result, Aug. 9 6 scar solid some indefinite pelvic pain question of adhesions.

CASE 7. N 3 780 Age 3 M Comminuted fracture of femur. Operation, Oct. 28 either Dr F B Lund, application of bone band. Post-operative diagnosis, same. Complications, some post-operative shock for twenty-four hours. Discharged Nov 8 band healed fragments in excellent position using crutches. Result Aug. 9 6 patient walks with cane not examined.

CASE 8. N 3 7537 Age 39 M Fracture of both bones of leg. Operation, Oct. 28 either Dr F B Lund, application of bone band to tibia. Post-operative diagnosis, same. Complications, none. Discharged Nov 20 wound healed fracture in good position crutches. Result Mar. 9 6 band removed on account of slight swelling M y 9 6 union and practically perfect position.

CASE 9. No. 3 7031 Age 40 M N. vomiting and epigastric pain. Pre-operative diagnosis, carcinoma of stomach. Operation, Oct. 26 either Dr F B Lund, large nodular mass filling half of stomach inoperable exploratory laparotomy. Post-operative diagnosis, same. Complications, none. Discharged Nov 6 wound healed. Died about three months after operation.

CASE 20. No. 3 7556 Age 45 M Pain and swelling in epigastric erection of gas. Pre-operative diagnosis, epigastric hernia. Operation, Oct. 7 either D E H. Nichols, hernia repaired stomach normal Post-operative diagnosis same. Complications, none. Discharged Nov 24 wound healed. Result, Jul. 9 6 all until two or three months ago when he began to have pain after eating loss of appetite nausea mucus in stools. For week has been unable to work examination negative.

CASE. No. 3264 6. Age 30 M Oct. 9 suture of perforated ulcer of anterior wall of pylorus, gastro-enterotomy planned for Oct. 7. Pre-operative diagnosis, gastric ulcer. Operation, Oct. 27, either, Dr E H Nichols, posterior gastro-enterostomy. Complications, tonsillitis. Discharged Nov 8, relieved condition excellent. Result, July 9 6, on troubles except muscular rheumatism and some gastric pain about four weeks ago.

CASE. No. 3 7834. Age 4 M Tumor of breast 5 months' duration. Pre-operative diagnosis, carcinoma. Operation, Oct. 3 either Dr H A Lothrop, amputation of breast dissection of axilla. Post-operative diagnosis, same. Complications, none. Discharged Nov 5 wound healed.

CASE 3. No. 32046 Age 20 M Fracture of pelvis rupture of urethra. External urethrotomy. Oct. Operation, Oct. 3 either Dr H A Lothrop, catheter passed. Complications secondary urethrotomy on account of stricture, Nov Discharged Feb. 9 6 relieved. Result July 9 6 table to work on account

of pain and weakness I region of pubes. Urethral condition good X ray shows sound healing of pelvis not much deformity.

CASE 14. N 3 7835 Age 46 M Carbuncle on neck. Operation Oct. 3 gas Dr H A Lothrop infection. Discharged Nov 4 relieved wound granulating.

CASE 5. N 3 7007 Age 4 M Pain in right lower quadrant. Pre-operative diagnosis acute appendicitis. Operation, Oct. 8 either, Dr H A Lothrop appendectomy. Post-operative diagnosis same. Appendix perforated, with peritonitis. Complications, none. Discharged, Nov 6 relieved, with small scars. Result July 9 6 working since Jan cannot do heavy lifting examination shows weak place in scar; no hernia.

CASE 26. No. 3 7054 Age 43 F Pal in lower abdomen. Pre-operative diagnosis, probably appendicitis. Operation, Oct. 20 either Dr H A Lothrop drainage of pelvic abscess, appendix not found. Post-operative diagnosis same. Complications none. Discharged Nov. relieved small scars. Result J. 9 6 troubled with constipation since operation no other symptoms.

CASE 7. No. 3 704 Age 58 F Prolapsus. Operation Oct. 26 either Dr Frederick J Cotton, vaginal hysterectomy perineorrhaphy. Complications, recurrence of cystocele. Discharged Nov 20 general condition good curing pessary.

CASE 8. N 3 7 40 Age 44 M Bleeding from rectum with loss of eight. Pre-operative diagnosis, ? of carcinoma of sigmoid. Operation, Oct. 26 either, Dr Frederick J Cotton sigmoid thickened, on sign of carcinoma, proctectomy. Post-operative diagnosis, colitis. Complications, none. Discharged Nov 8 small scars. Under irrigation colitis with attendant mucus and blood entirely disappeared. On account of inconvenience from the occasional reopening of appendicostoma operation for removal of appendix was done Jul. 20 9 6.

CASE 29. N 3 78 Age 4 M Crab-foot. Operation Oct. 26 either Dr Frederick J Cotton, incision of plantar fascia, foot put up in plaster. Complications, none. Discharged Nov 6 wound healed crutches.

CASE 30. N 3 7750 Age 5 Acetia with jaundice. Pre-operative diagnosis, chrysis of liver. Operation, Oct. 26 either Dr Frederick J Cotton omentectomy. Complications, bronchopneumonia peritonitis. Discharged Oct. 30 dead. A tapeworm showed peritonitis and bronchopneumonia.

CASE 3. N 3 7031 Age 3 M Fracture of femur with overriding. Operation Oct. 8 either Dr Frederick J Cotton application of bone band. Complications none. Discharged Dec. 4 wound healed fragments in good position.

CASE 3. No. 3277 Age 49 F Fractured fibula, Cotton fracture. Operation Oct. 28 either Dr Frederick J Cotton reduction by manipulation plaster. Complications none. Discharged Nov 6 fragments in good position plaster and crutches. Result Aug. 9 6 no evident deformity no limp walking.

CASE 33. N 3 7483 Age 3 F Fracture of jaw. Operation Oct. 8 either Dr Frederick J Cotton, wiring of fragments. Complications, none. Discharged Nov. relieved, went to dentist. Result July 9 6 slight deformity excellent result.

CASE 34. N 327920 Age 50 F Fracture of neck of femur. Operation, Oct. 8 either Dr Frederick J Cotton, impaction of fragments. Complications, conjunctivitis mediastinal abscess. Discharged Dec. 6 general condition weak using crutches. Result, July 9 6 not as yet very useful result still uses crutch X ray shows solid union good position question whether union

is strictly boy patient feeble not able to make use of what function he has

CASE 52, N 3 4 Age 18 Salpingitis with
pel catarrh, Oct annual drainage of pel base 2

Operation Oct. 7 ether Dr Frank H. Lahey salpingectomy. Complications, none. Discharged Nov. 3, against advice; profuse discharge from wound general condition excellent. Result, Aug., 9 6 letter states that there are no symptoms relative to operation but is anxious and has lost pounds.

CASE 60. No. 337803. Age 20 F. Colloid goiter. Operation Oct. 28 Dr Frank H. Lahey scopolamine morphine and novocaine, lobectomy partial. Post-operative diagnosis, simple adenoma. Complications, some difficulty in swallowing. Discharged, Oct. 3 wound healed. Result, Aug. 9 6 no prominence in neck pressure on swallowing still persists.

CASE 61. No. 337839. Age 55 M. Persistent sinus, chronic emphysema. Operation, Oct. 8 ether Dr Frank H. Lahey resection of ribs, decortication of lung. Complications, none. Discharged Nov. 3 sinus requires no dressing a day.

CASE 62. N. 337976. Age 3, M. Acute appendicitis. Operation, Oct. 7 ether Dr Halsey B. Loder appendectomy, appendix gangrenous. Post-operative diagnosis, same. Complications, none. Discharged Nov. 10. Itch small sinus. Result, July 19 6 patient says wound did not heal for 3 months now has no symptoms tumor about above broad parietal scar, no hernia.

CASE 63. No. 35033. Age 3 F. Pain in right lower quadrant, 9 days duration. Pre-operative diagnosis, appendicitis. Operation, Oct. 20, ether Dr Halsey B. Loder double salpingectomy. Post-operative diagnosis, salpingitis. Complications, none. Discharged Nov. 3 wound healed. Result July 9 6 reports by letter that she never felt better in her life and operation did her world of good.

CASE 64. No. 35535. Age 35 F. Varicose clots. Operation, Oct. 20 ether Dr Halsey B. Loder multiple ligations. Complications, bronchitis. Discharged Nov. 3 wound healed. Result, Jul. 9 6 little pain once while works in laundry examination shows ideal result.

Gynecological Service

CASE 65. No. 3705. Age 30. Backache. Pre-operative diagnosis, lacerated perineum. Operation Oct. 20 ether Dr Ernest B. Young D & C trachelorrhaphy anterior and posterior colporrhaphy. Complications, alveolar abscess. Discharged Nov. 10 dental wound healed. Last result, patient could not be traced.

CASE 66. No. 3744. Age 43. Lacerated cervix and perineum. Operation Oct. 21 ether Dr Ernest B. Young D & C, trachelorrhaphy anterior and posterior colporrhaphy. Complications, none. Discharged Nov. 8 relieved wound healed. Result Aug. 9 6 excellent result patient has enteropneumia and is undergoing change of life feel nervous.

CASE 67. No. 377. Age 30. Rectocele, ystocoele. Operation, Oct. 7 ether Dr Ernest B. Young D & C, anterior and posterior colporrhaphy. Nov. 9, central fixation and ligation of both tubes. Complications, none. Discharged Nov. 10 wound healed. Result Aug. 9 6 excellent anatomical result good perineal support no prolapse patient comfortable.

CASE 68. N. 338003. Age 43. Leucorrhoea. Pre-operative diagnosis, endocervicitis. Operation, Oct. 20 ether Dr Ernest B. Young D & C, cauterization of cervix with thermal cautery. Complications, none. Discharged Nov. 10 relieved. Result, July 9 6 still has discharge much improved as at time 1 some pain in right side pelvic examination entirely negative.

CASE 69. No. 3783. Age 60. Prolapsed uterus. Operation, Oct. 20 ether Dr Ernest B. Young anterior colporrhaphy perineorrhaphy ventral fixation. Com-

plications, none. Discharged Nov. 8 condition excellent. Last result, patient could not be traced.

CASE 70. N. 37780. Age 3. Salpingitis. Operation, Oct. 20 ether Dr Ernest B. Young left salpingectomy ventral suspension. Complications, none. Discharged Nov. 9, wound healed. Result, July 9 6 well until January when she fell the leg since then has had pain low in abdomen and metrorrhagia has lost pounds.

CASE 71. No. 3735. Age 40. Ovarian cyst. Operation Oct. 5 ether Dr Nathaniel R. Mason removal of large ovarian cyst appendectomy. Post-operative diagnosis, dermoid cyst of ovary. Complications, phlebitis of left leg. Discharged Nov. 5 condition excellent. Result, Jul. 9 6 does not feel ill since operation, mostly troubled with left leg some trouble with right and when 1 work left leg tender no signs of old phlebitis.

CASE 72. N. 37304. Age 7. Lacerated perineum. Operation Oct. 5 ether Dr Nathaniel R. Mason, D & C trachelorrhaphy colpoperineorrhaphy. Complications, none. Discharged Nov. 8 condition excellent.

CASE 73. N. 3765. Age 20. Backache for 4 years in previous operations without relief. Pre-operative diagnosis, lacerated perineum. Operation, Oct. 20 ether Dr Nathaniel R. Mason, D & C trachelorrhaphy colpoperineorrhaphy. Complications, none. Discharged Nov. 8 condition excellent. Result, July 9 6 she feels more pain in the back and hip than before operation. Examination reveals infiltration of right adnexa not present 1 time of operation.

CASE 74. N. 3786. Age 20. Menorrhagia. Pre-operative diagnosis, endometritis. Operation, Oct. 7 ether Dr Nathaniel R. Mason, curettage curettings negative. Complications, none. Discharged Nov. 10 relieved.

CASE 75. N. 17880. Age 10. Miscarriage 1 month. Operation, Oct. 7 ether Dr Nathaniel R. Mason curettage. Complications, none. Discharged Nov. 4, relieved.

CASE 76. N. 3767. Age 20. Bearing-down pain. Pre-operative diagnosis, retroversion. Operation Oct. 7 ether Dr Nathaniel R. Mason central fixation. Complications, none. Discharged Nov. 10 relieved wound healed. Result July 9 6 no symptoms however firm scar pelvis free.

CASE 77. N. 3786. Age 7. Miscarriage 13 months. Operation Oct. 21 ether Dr Nathaniel R. Mason curettage. Complications, none. Discharged Nov. 4, relieved.

CASE 78. N. 3796. Age 20. Miscarriage 1 month. Operation Oct. 8 ether Dr Nathaniel R. Mason, curettage. Complications, none. Discharged Nov. 6 relieved. Result Jul. 9 6 perfect relief general condition excellent no trouble in periods since operation.

CASE 79. N. 17864. Age 20. Endometritis. Operation Oct. 8 ether Dr Nathaniel R. Mason, D & C, trachelorrhaphy. Complications, none. Discharged Nov. 7 relieved. Result July 9 6 pain left and persisted all inter pregnancy in March miscarriage 15 or 6 weeks curettage perfectly efficient.

CASE 80. N. 37953. Age 20. Lacerated perineum. Operation Oct. 20 ether Dr Nathaniel R. Mason, D & C trachelorrhaphy posterior colpoperineorrhaphy. Complications, none. Discharged Nov. 3 wound healed.

CASE 81. N. 37783. Age 40. Lacerated cervix. Operation Oct. 20 ether Dr Nathaniel R. Mason D & C trachelorrhaphy. Complications, none. Discharged Nov. 10 relieved.

CASE 82. N. 376. Age 30. Lacerated cervix and perineum. Operation Oct. 5 ether Dr John T.

Williams, D & C trachelorrhaphy anterior and posterior colporrhaphy. Complications vomited for one week cause unknown. Discharged Nov 8 condition excellent. Result, July 916 condition good vomit when exerted.

CASE 83 No 327440 Age 23 Lacerated perineum. Operation Oct 25 either Dr John T Williams D & C trachelorrhaphy posterior colporrhaphy. Broke piece of needle, which could not be found left in perineum. Complications, no symptoms from broken needle. Discharged Nov 8 condition excellent. Result, July 916 condition good occasional pain in right side.

CASE 84 No 3865 Age 20 M. Carnage. Operation, Oct 26 Dr John T Williams urethra. Complications none. Discharged Nov 8 condition excellent. Result, August, 916 condition excellent. No further discharge. Months pregnant.

Aural Series

CASE 85 No 3865 Age 10 M. Chronic discharge from ear. Pre-operative diagnosis chronic otitis media and mastoiditis. Operation, Oct 26 either Dr Corn, A Leland simple excision. No radical operation done. Complications no lateral sinus thrombosis. No jugular tied. Discharged Nov 8 dead.

CASE 86 No 32850 Age 10 M. Chronic discharge from ear. Pre-operative diagnosis chronic otitis media and mastoiditis. Operation, Oct 27 either Dr J. M. Himes mastoidectomy. Complications none. Jugular tied and radical mastoidectomy. Discharged Nov 8 condition excellent. Result, July 916 ear dry and healed. Result, July 916 small scar. Hearing normal in both ears. Roughly.

Throat Series

Twenty-four operations for removal of tonsils and adenoids were performed by Dr Edg. M. Holmes. With complications and with satisfactory immediate result. Late results obtained in 6 cases. Throat in excellent condition in all. One case now has a discharging ear.

BOSTON DISPENSARY

Twenty-Five Cases

Surgical Series

CASE 1 No 10343 Age 4 M. Varicose vein. Operation Oct 27 cocaine. Dr Henry M. Chase ligation and excision of internal saphenous vein and below knee. Complications none. Late result, July 1916 entire freedom from symptoms of venous origin. Flat foot causes some discomfort.

CASE 2 No 10269 Age 30 M. Varicose vein. Operation Oct 27 cocaine and novocaine. Dr Henry M. Chase, ligation and excision groin and below knee. Complications died on seventh day suddenly with obvious cause. Embolism. No autopsy.

CASE 3 No 12470 Age 40 J. Varicose vein and ulcer. Operation Oct 9 cocaine and novocaine. Dr Hubert F. Day ligation and excision of internal saphenous vein and below knee and ulcer. Complications none. Above ulcer slightly infected. Late result, July 916 ulcer healed. No enlarged veins. No pain. Very kind.

CASE 4 No 103353 Age 54 J. Ingrowing toe nail. Operation, Oct 29 cocaine. Dr Oliver C. Tinkham excision of border of nail and matrix. Complications none. Late result Aug 1916 excellent.

CASE 5 No 9356 Age 25 J. Ingrowing toe nail. Operation Oct 2 cocaine. Dr Oliver C. Tinkham excision of border of nail and matrix. Complications none. Late result Jun 1916 excellent.

CASE 6 No 93360 Age 6 M. Ingrowing toe nail. Operation Oct 2 cocaine. Dr Oliver C. Tinkham excision of border of nail and matrix. Complications none. Late result Jul 1916 perfect result.

ham excision of border of nail and matrix. Complications none. Late result Jun 1916 excellent.

CASE 7 No 9355 Age 4 M. Hernia. Operation Oct 2 either Dr J. M. Himes or Dr J. M. Himes.

CASE 8 No 9355 Age 4 M. Hernia. Operation Oct 2 either Dr J. M. Himes or Dr J. M. Himes.

CASE 9 No 9355 Age 4 M. Hernia. Operation Oct 2 either Dr J. M. Himes or Dr J. M. Himes.

CASE 37 No 9355 Age 4 M. Hernia. Operation Oct 2 either Dr J. M. Himes or Dr J. M. Himes.

CASE 38 No 9355 Age 4 M. Hernia. Operation Oct 2 either Dr J. M. Himes or Dr J. M. Himes.

CASE 39 No 9355 Age 4 M. Hernia. Operation Oct 2 either Dr J. M. Himes or Dr J. M. Himes.

CASE 40 No 9355 Age 4 M. Hernia. Operation Oct 2 either Dr J. M. Himes or Dr J. M. Himes.

CASE 41 No 9355 Age 4 M. Hernia. Operation Oct 2 either Dr J. M. Himes or Dr J. M. Himes.

CASE 42 No 9355 Age 4 M. Hernia. Operation Oct 2 either Dr J. M. Himes or Dr J. M. Himes.

CASE 43 No 9355 Age 4 M. Hernia. Operation Oct 2 either Dr J. M. Himes or Dr J. M. Himes.

CASE 44 No 9355 Age 4 M. Hernia. Operation Oct 2 either Dr J. M. Himes or Dr J. M. Himes.

CASE 45 No 9355 Age 4 M. Hernia. Operation Oct 2 either Dr J. M. Himes or Dr J. M. Himes.

Three cases were operated upon for deviated septum, one complicated by polyp and necrosis of turbinate. No post-operative complications. Late results obtained in 3 cases, anatomically excellent in both. In one case patient states sense of smell lost, in another headaches continue.

BOSTON LYING-IN HOSPITAL

One Case

CASE. No. 32003. Age 23. Pre-operative diagnosis, dystocia just prior to delivery. Operation, Oct. 5 either Dr. J. R. Torbert, cesarean section. Post-operative diagnosis, same. Complications, none. Discharged Nov. mother and baby well. Result, June, 9, 6, wound solid uterus in normal position no symptoms, baby well.

PETER BENT BRIGHAM HOSPITAL

Twenty-five Cases

CASE. N. 6702. Age 14 F. Came for relief of focal epilepsy and blindness. Pre-operative diagnosis, focal epilepsy (left arm). Operation, Oct. 5 either Dr. Harvey Cushing, osteoplastic exploration of right hemisphere. Post-operative diagnosis, same old meningio-encephalitis. Complications, none. Discharged Nov. 3 condition unchanged. Late result, June, 9, 6 condition unchanged.

CASE. No. 6557. Age 55 F. Came for relief of pain in, and enlargement of, abdomen. Pre-operative diagnosis, ovarian cyst. Operation, Oct. 5 either Dr. John Homans, exploratory laparotomy. Post-operative diagnosis, general carcinoma, large mass in left abdomen, carcinoma of omentum. Complications, none. Discharged Nov. 18 unimproved. Patient died Mar. 8, 9, 6 evidently of the disease found at operation. N. 6707.

CASE. No. 6855. Age 28 F. Came for relief of pain and frequency of micturition pain in right lumbar region. Pre-operative diagnosis, tuberculosis pyonephrosis. Operation, Oct. 5 either Dr. David Cheever right hemi-plectomy. Post-operative diagnosis, same. Complications, none. Discharged Nov. 9 improved. Lat. result, patient could not be traced.

CASE. No. 6035. Age 20 F. Came for relief of swelling in left groin 3 years duration. Pre-operative diagnosis, left inguinal hernia. Operation, Oct. 5, either Dr. David Cheever closure of direct inguinal hernia. Post-operative diagnosis, same. Complications, none. Discharged Nov. 8 relieved. Lat. result, patient could not be traced.

CASE. No. 6890. Age 35 F. Came for relief of lump in right breast. Operation, Oct. 5, 9, 5 for local removal of tumor reported benign at first but later proved to be malignant by microscopic examination. Pre-operative diagnosis, carcinoma of breast. Operation, Oct. 26, either Dr. David Cheever secondary excision of pectoral muscles, with dissection of ribs. Post-operative diagnosis, same. Complications, secondary skin graft 25 days after operation. Discharged Nov. 5 relieved. Lat. result, patient reports by letter that there is some swelling and weakness of arm local doctor report no evidence of return of the disease.

CASE. No. 6039. Age 38 M. Came for relief of difficulty in walking, dizziness, headache, and convulsions. Pre-operative diagnosis, tumor of right cerebral hemisphere. Operation, Oct. 26 Dr. Harvey Cushing right subtemporal decompression. Post-operative diagnosis, same. Complications, condition excellent until 7 p.m. when severe epileptiform attack occurred with death within a short time without regaining consciousness.

Autopsy endothelioma of the brain (right frontal lobe) probably operable subdural hemorrhage 1st of decompression wound beginning bronchopneumonia arteriosclerosis.

NOTE. On the morning of operation, the patient had Jacksonian seizure, involving his left hand no doubtless had the Congress not been present, this would have been brought to the attention of the operator and the operation postponed. Under these circumstances, subtemporal decompression was an incorrect measure, and he should have had an osteoplastic resection exposing the hand center which would have disclosed the tumor an easily accessible growth. It is the sort of accident that is more likely to occur under the pressure of work while entertaining large body of visitors, and is one of the reasons why I feel that on the whole, though these Congresses may be unproductive to the onlooker they often put the patient at disadvantage.—H. C.

CASE. N. 6090. Age 45 F. Came for relief of varicose veins and ulcer 20 years' duration umbilical hernia. Pre-operative diagnosis, same. Operation, Oct. 26, either Dr. John Homans, excision of internal saphenous vein by stripping no dissection excision of ulcer Nov. 6 repair of umbilical hernia under novocain Nov. 6, skin-graft for ulcer. Discharged relieved, Dec. 5, 9, 6. Lat. result, July, 9, 6 no swelling ulcer recently healed patient done her work has on bandages until recently good result.

CASE. N. 6048. Age 37 F. Came for relief of pain in lower right abdomen 3 days' duration. Pre-operative diagnosis, chronic salpingitis with exacerbation. Operation, Oct. 26 either Dr. John Homans, double salpingo-oophorectomy uterus not disturbed. Post-operative diagnosis, same. Complications, none. Discharged Nov. 9 relieved. Lat. result, June, 9, 6 (obtained by letter) patient considers herself improved but still suffers from the symptoms which brought her to the hospital.

CASE. N. 6033. Age 54, F. Came for relief of pain in upper right quadrant, of 8 years' duration. Pre-operative diagnosis, cholelithiasis and cholecystitis. Operation, Oct. 26 either Dr. David Cheever cholecystectomy excision of multiple pancreatic cysts. Post-operative diagnosis, same plus multiple cysts of pancreas. Complications, abundant discharge of clear fluid from wound no discoloration of skin. Discharged relieved, Dec. 6, 9, 6. Lat. result, July, 9, 6 wound finally healed and gives no discomfort feels well no symptoms.

CASE. N. 6814. Age 34 M. Came for relief of gastric distress and vomiting 4 weeks' duration. Pre-operative diagnosis, acute bleeding ulcer. Operation, Oct. 7 either Dr. John Homans, iliocecal pyroplasty section of indurated tissue removed. Post-operative diagnosis, suppurative gastritis induration of gastric wall no ulcer. Complications, none. Discharged Nov. 5 relieved. Lat. result, July, 9, 6 wound solid has gained 30 pounds occasional crampy pain in epigastrium and appendicular region no indigestion. Excellent result, but should have had appendix removed.

CASE. No. 603. Age 51. Came for relief of blindness. Pre-operative diagnosis, acromegaly 15th loss of vision. Operation, Oct. 7 either Dr. Harvey Cushing transphenoidal operation with partial removal of pituitary tumor. Post-operative diagnosis same struma of hypophysis. Complications, none. Discharged Nov. 9, relieved. Lat. result, July, 9, 6 marked subsidence of symptoms with improvement of vision.

CASE. No. 6838. Age 51. Came for relief of stomach trouble pain and hematemesis, three months duration. Pre-operative diagnosis, gastric ulcer or ca.

CASE 3. No. 306. Age 35 F. Menorrhagia. Pre-operative diagnosis, myoma of uterus. Operation, Oct. 3, ether. Dr. John T. Bottomley supravaginal hysterectomy-omphorectomy. Post-operative diagnosis, same. Complications, peritonitis (see note). Discharged Oct. 30, dead.

CASE 4. N. 3064. Age M. Pain in right knee. Pre-operative diagnosis, sarcoma of right fibula. Operation, Oct. 5, ether. Dr. John T. Bottomley excision of upper end of fibula, external popliteal nerve cut. Post-operative diagnosis, same. Complications, none, except foot-drop. Discharged Dec. 1 to Nerve Department. Lat. result July 19, 6 wearing leg brace and doing well. Last report.

CASE 5. No. 046. Age 75 M. Urinary retention. Pre-operative diagnosis, hypertrophied prostate. Operation, Oct. 5 spinal anesthesia. Dr. Daniel F. Mahoney suprapubic prostatectomy (first stage of operation suprapubic cystostomy having been performed Oct. 6, 9, 5). Post-operative diagnosis, same. Complications, none. Discharged Nov. 26 relieved. Late result June, 9, 6 greatly improved, gets up once at night to urinate but only occasionally.

CASE 6. No. 3040. Age 25 M. Pre-operative diagnosis, inguinal hernia. Operation, Oct. 3, ether. Dr. Daniel F. Mahoney Bassini operation. Post-operative diagnosis, same. Complication, tuberculous meningitis. Discharged Nov. 3, dead.

CASE 7. No. 975. Age 45 F. Epigastric pain and vomiting. Pre-operative diagnosis, probable duodenal ulcer. Operation, Oct. 7, ether. Dr. John T. Bottomley posterior gastro-entostomy. Post-operative diagnosis, same. Complications, none. Discharged Nov. 12 relieved in excellent condition. Late result, unknown.

CASE 8. N. 3068. Age 60, F. Tumor of right breast. Pre-operative diagnosis, carcinoma. Operation, Oct. 7, ether. Dr. John T. Bottomley radical breast operation. Post-operative diagnosis, same. Complications, sepsis (see note). Discharged Nov. 3, dead.

CASE 9. No. 3047. Age 55 F. Abdominal tumor. Pre-operative diagnosis, ovarian cyst? Operation, Oct. 27, ether. Dr. John T. Bottomley removal of ovarian cyst. Post-operative diagnosis, ovarian cyst. Complications, sepsis (see note). Discharged Nov. 9, dead.

CASE 10. No. 3077. Age 40, M. Pre-operative diagnosis, incarcerated inguinal hernia. Operation, Oct. 20, ether repair of hernia (Andrews-Ferguson method). Post-operative diagnosis, same. Complications, local infection (see note). Discharged Dec. 3, relieved. Lat. result, June, 9, 6 wound healed, no impulse, condition good.

CASE 11. No. 3070. Age 50 M. Epigastric pain. Pre-operative diagnosis, cancer of stomach. Operation, Oct. 20, ether. Dr. John T. Bottomley posterior gastro-entostomy. Post-operative diagnosis, same. Complications, none. Discharged Nov. 30, relieved. Late result, died Apr. 7, 9, 6 had great relief for about two months.

CASE 12. N. 3060. M. Growth on tongue. Pre-operative diagnosis, cancer. Operation, Oct. 20, ether. Dr. John T. Bottomley dissection of both sides of neck (first stage) radical removal of growth. N. 24, 9, 5 (second stage). Post-operative diagnosis, same. Complications, none. Discharged Dec. 24, relieved. Lat. result, unknown.

Gynecological Service

CASE 1. No. 2446. Age 40. Came for relief of foul vaginal discharge. Pre-operative diagnosis, cancer of cervix. Operation, Oct. 6, gas and ether. Dr. Stephen Rushmore, panhysterectomy (radical) double salpingo-

omphorectomy. Post-operative diagnosis, same plus cholelithiasis. Complications, some breaking down of wound, serous discharge but no pus. Discharged Nov. 24, relieved. Late result, patient was admitted at another hospital Jan. 9, 6. X-ray examination suggested cancer of the stomach. V. operation. Death occurred in two weeks.

CASE 2. N. 2445. Age 37. Pain in pelvis and back. Pre-operative diagnosis, laceration of perineum, descensus of uterus with retroversion. Operation, Oct. 26, gas and ether. Dr. Stephen Rushmore, perineorrhaphy, appendectomy, shortening of ternal sacral ligaments, round ligament suspension of uterus (Kelly). Post-operative diagnosis, same. Complications, induration of incision but no breaking down. Discharged Nov. 3, relieved. Late result July 9, 6 anatomical result excellent, relieved of complaints on admission but complaints of occasional tenderness in incision.

CASE 3. No. 2444. Age 43. Menorrhagia. Pre-operative diagnosis, myoma of uterus, umbilical hernia. Operation, Oct. 6, gas and ether. Dr. Stephen Rushmore, supra-umbilical hysterectomy, double salpingo-omphorectomy, radical cure of hernia. Post-operative diagnosis, same. Complications, none. Discharged Nov. 10, relieved. Late result, July 19, 6 anatomical result excellent, never felt better in her life, hot flashes troublesome at first.

CASE 4. N. 2444. Age 43. Uterine hemorrhage. Pre-operative diagnosis, metropathy. Operation, Oct. 26, gas and ether. Dr. F. W. Johnson, panhysterectomy, double salpingo-omphorectomy. Post-operative diagnosis, multiple myomas. Complications, suppuration of abdominal wound. Discharged Dec. 8, relieved. Late result July 9, 6 anatomical result excellent, patient is well except for slight nervousness and mental depression, which is improving.

CASE 5. N. 2447. Age 53. Falling of womb. Pre-operative diagnosis, laceration of cervix and perineum, cystocele, rectocele and procidentia. Operation, Oct. 26, gas and ether. Dr. F. W. Johnson, D. & C. amputation of cervix, Watkins operation, perineorrhaphy. Post-operative diagnosis, same. Complications, none. Discharged Nov. 3, relieved. Lat. result July 9, 6 anatomical result excellent, well so far as pelvic symptoms are concerned, rheumatism of back and legs.

CASE 6. N. 2448. Age 50. Severe pain no right side of pelvis. Pre-operative diagnosis, procidentia. Operation, Oct. 26, gas and ether. Dr. L. E. Phaneuf, D. & C. amputation of cervix, resection of left ovary, appendectomy, suspension of uterus (Olshausen). Post-operative diagnosis, same. Complications, stitch abscess. Discharged Nov. 3, relieved. Late result, July 9, 6 anatomical result excellent, general health good, occasional pelvic discomfort, symptoms for which she came to the hospital are gone, she says.

CASE 7. N. 2445. Age 3. Pain in pelvis. Pre-operative diagnosis, laceration of cervix and perineum, chronic pelvic inflammation. Operation, Oct. 8, gas and ether. Dr. Stephen Rushmore, D. & C. perineorrhaphy, supravaginal hysterectomy (bi-section), double salpingo-omphorectomy. Post-operative diagnosis, same. Complications, none. Discharged Nov. 6, relieved. Late result, July 9, 6, excellent, patient feels perfectly well, occasional hot flashes which are growing less.

CASE 8. No. 2450. Age 45. Menorrhagia. Pre-operative diagnosis, metropathy. Operation, Oct. 26, gas and ether. Dr. F. W. Johnson, panhysterectomy, double salpingo-omphorectomy, appendectomy. Post-operative diagnosis, same. Complications, peritonitis. Discharged Nov. 6, dead.

CASE No. 634. Age 9 F. Pre-operative diagnosis, spleen infarct (infected). Operation, Oct. 5 either Dr. James S. Stone, excision of sac. Post-operative diagnosis, same. Complications infection of wound. Discharged Nov. 4, relieved. Result, Aug. 19 6 perfect scar solid, no paralysis, walks perfectly.

CASE 5. N. 6858. Age 4 F. Cervical adenitis, tuberculous. Operation, Oct. 5, either Dr. W. E. Ladd dissection of neck, removal of tonsils and adenoids. Post-operative diagnosis, same. Complications, none. Discharged Nov. 5 relieved. Result Aug. 9 6 inconspicuous scars in crease of neck, one or two small palpable glands.

CASE 4. No. 6859. Age months, F. Harelip and cleft palate. Operation, Oct. 5 either Dr. W. E. Ladd cheloplasty palat. to be operated on at year. Complications, none. Discharged Nov. 5 wound healed. Result, Aug. 9 6 very good result. Inconspicuous scar.

CASE 5. N. 6867. Age 4 M. Hypospadias. Operation, Oct. 5 either Dr. C. G. Mixer Beck operation. Complications, fistula. Site of old urethral opening. Discharged Nov. 8 small fistula. Result March, 916 secondary operation for closure of fistulous opening. Flaps sloughed. Result, Aug., 9 6 small stream of urine passes out of tip of glans through tunnel greater portion voided through fistulous opening.

CASE 6. N. 5883. Age 3 months, M. Angioma of forehead. Operation, Oct. 5 no anesthetic. Dr. T. W. Harmer application of liquid air. Discharged same day. Result, Aug. 9 6 scarcely noticeable scar.

CASE 7. No. 5888. Age 6 months, F. Ca. excruciating pain of parotid and ear. Operation, Oct. 5 either Dr. T. W. Harmer electrolysis. Discharged same day. Late result not known.

CASE 8. N. 585. Age 7 months. Cleft palate. Operation Oct. 26 either Dr. James S. Stone, staphylothyphary. Complications, none. Discharged Nov. 5 complete union. Result, Aug. 9 6 marbled gain in general health. Speech is reported indistinct but is doing well in school.

CASE 9. N. 6856. Age 7 M. Inguinal hernia. Operation Oct. 26 either Dr. C. G. Mixer repair of hernia (Ferguson). Complications none. Discharged Nov. 5 relieved. Result, Aug. 916 wound solid no recurrence no symptoms.

CASE N. 5624. Age F. Cleft palat. Operation, Oct. 27 either Dr. James S. Stone, staphylothyphary. Complications, chicken pox. Discharged N. 5 union of hard and anterior half soft palat. Lat. result, Aug. 9 6 partial success needs further operation on soft palat.

CASE 1. No. 6833. Age 3 F. Tumor of bladder. Operation, Oct. 7 either Dr. C. G. Mixer exploratory specimen removal, reported sarcoma. Secondary operation Nov. 7 partial extraperitoneal cystectomy. Result, Aug., 9 6 wound healed feels well urine normal cytoscopic shows no sign of recurrence.

CASE No. 6785. Age 4 F. Burn of arm. Operation, Oct. 26 either Dr. T. W. Harmer Thiersch graft. Complications, child fractures displaced grafts. Late result unknown.

CASE 3. No. 6873. Age 3 M. Inguinal hernia. Operation, Oct. 7 either Dr. T. W. Harmer repair of hernia (Ferguson). Complications, none. Discharged Nov. 4, wound healed. Result, Aug. 9 6 wound solid, no recurrence.

CASE 14. No. 687. Age 4, M. Inguinal hernia. Operation, Oct. 26 either Dr. James S. Stone. Repair of inguinal hernia (Ferguson). Complications none. Discharged Nov. 7 wound healed. Result, Aug. 9 6 perfect in every way.

CASE 5. No. 6855. Age month, M. Double harelip. Operation Oct. 8 either Dr. W. E. Ladd cheloplasty

Complications, none. Discharged relieved wound healed. Result, July 9 6 excellent.

CASE 6. N. 34. Age 3 F. Cleft palate. Operation, Oct. 8 either Dr. C. G. Mixer staphylothyphary. Complications, soft palate pulled away. Discharged relieved complete union of hard palate. Result, Aug. 19 6 hard palate united soft palate partially united there is cleft on quarter inch in length including the uvula pharyngeal fall.

CASE 7. N. 6876. Age months, F. Cutaneous angioma of arm. Operation Oct. 26 either Dr. T. W. Harmer excision. Complications, post-operative pyrexia. Discharged Nov. 4 wound healed. Result, July 9 6 no recurrence, scar soft.

CASE 8. No. 450. Age M. Cleft palat. Operation, Oct. 29 either Dr. James S. Stone staphylothyphary. Complications none. Discharged Nov. 9 union of hard and anterior half of soft palate. Result, Aug. 9 6 posterior half of soft palat. not united, needs further operation.

CASE 9. N. 6860. Age 3 F. Double inguinal hernia. Operation Oct. 29, either Dr. J. S. Stone repair of hernia. Complications none. Discharged Nov. 14, wounds healed. Result, Aug. 9 6 result excellent in every way.

CASE 20. No. 6870. Age 7 M. Cervical adenitis. Operation, Oct. 29 either Dr. W. E. Ladd, dissection of neck. Complications none. Discharged Nov. 5 wound healed. Result, Aug. 9 6, inconspicuous scar no palpable glands, general condition excellent.

CASE No. 6870. Age 8 F. Inguinal hernia. Operation Oct. 29 either Dr. C. G. Mixer repair of hernia (McEwen). Complications, none. Discharged relieved wound healed. Result, Aug. 9 6 wound solid perfect result.

Orthopedic Series

CASE N. 6835. Age 9, F. Contracture of tendo lacus (remors) (infantile paralysis). Operation, Oct. 5 either Dr. R. M. Lovett, double f. sclerotomy and myotomy of tendo lacus (remors). Complications none. Discharged relieved. Result July 9 6, legs can be hyperextended walking with braces and crutches, good result.

CASE 23. N. 6846. Age F. Knock-knee. Operation, Oct. 25 either Dr. Augustus Thorndill osteotomy (McEwen). Complications, none. Discharged relieved. Result, July 9 6 legs in good position walking without apparatus.

CASE 24. N. 686. Age 5 M. Torticollis, congenital. Operation Oct. 5 D. Augustus Thorndill, section of both heads of right sternocleid. Complications, none. Discharged, relieved. Result, July 1916 reports by letter lat. that child is doing well.

CASE 5. N. 6833. Age 5 F. Bow-legs. Operation, Oct. 5 either Dr. A. Ethelred, osteoclasis. Complications, none.

CASE 26. N. 6865. Age 6 M. Paralysis with contracture of tibialis anterior. Operation, Oct. 26 either Dr. R. M. Lovett, tendon transplantation anterior tibial to outer part of dorsum of foot. Complications, none. Discharged relieved. Result, June, 916 good anatomical result. Alls. 11th brace too early to record complete functional result.

CASE 27. No. 5547. Age 7 F. Infantile paralysis (hail-anke). Operation, Oct. 26 either Dr. Robert Souther astragaloctomy. Complications, none. Discharged relieved. Late result not known.

CASE 28. No. 6850. Age 4, F. Obstetrical paralysis. Operation, Oct. 26 either Dr. J. S. Stone Sever osteotomy of acromion division of subacromial tendon and portion of pectoralis major. Complications, none. Discharged

dilated cervix with erosion. Operation, Oct. 26 either Dr W P Graves, amputation of cervix supravaginal hysterectomy (first stage of operation) second stage done three weeks later. Post-operative diagnosis same. Complications, none. Discharged Dec 3. Results June, 96 anatomical condition good, slight elevation of perineum feels perfectly well no hot flashes.

CASE 5 N. 9857 Age 4. Came for relief of bearing-down pains, backache protrusion from vagina. Pre-operative diagnosis, wide distasia of recti muscles retroversion with prolapse rectocele uterol. Operation, Oct. 26 either Dr R. G. Wadsworth, dilatation and curettage trachelorrhaphy anterior colporrhaphy perineorrhaphy, appendectomy, posterior fixation of uterus approximation of recti muscles. Post-operative diagnosis same. Complications, considerable shock for 24 hours. Discharged Nov 5 relieved. Results June, 96 anatomical condition good slight recurrence of cystocele complete relief of backache some irritation of bladder to frequency of micturition.

CASE 6 N. 9866 Age 4. Came for relief of pain on sitting and discomfort from protrusion from vagina. Pre-operative diagnosis complete procidentia hypertriphed and elevated cervi. Operation Oct. 26 either Dr W P Graves, anterior colporrhaphy perineorrhaphy (second stage of operation. First stage had been done three weeks previous) Post-operative diagnosis same. Complications, none. Discharged Nov 5 relieved. Results June, 96 slight bulging at lower end of abdominal wound, results otherwise excellent, patient feels perfectly well no hot flashes.

CASE 7 N. 9855. Age 34. Came for the relief of dysmenorrhea and pain in left lower quadrant. Pre-operative diagnosis, retroversion. Operation Oct. 26 either Dr W P Graves, supravaginal hysterectomy appendectomy implantation of ovaries in situ. Post-operative diagnosis, retroversion pelvic inflammation. Complications, none. Discharged Nov 5 relieved. Results June, 96 anatomical condition excellent ovarian tissue palpable in abdominal wall no hot flashes.

CASE 8 N. 9867 Age 33. Came for relief of menorrhagia pain and tenderness in left lower quadrant. Operation three years previous for tubal pregnancy. Pre-operative diagnosis, supertuous uterus. Operation Oct. either Dr W P Graves supra vaginal hysterectomy lysis of adhesions. Post-operative diagnosis same. Complications, none. Discharged Nov 5 relieved. Results Dec 3. Used strong patient feels all.

CASE 9 N. 9868 Age 40. Came for relief of backache bearing-down pains frequency of micturition. Pre-operative diagnosis relaxation of vaginal outlet prolapse laceration of cervix. Operation Oct. 7 either Dr F A Pemberton, dilatation anterior colporrhaphy perineorrhaphy appendectomy fixation of round ligaments (Obhausen). Post-operative diagnosis same. Complications, none. Discharged Nov 6 relieved. Results June, 96 anatomical condition excellent patient much improved occasional discomfort in right lower pelvis.

CASE 10 N. 9874 Age 44. Came for relief of dysmenorrhea and sterility. Pre-operative diagnosis, fixation with retroversion. Operation, Oct. 7 either Dr F A Pemberton, dilatation, appendectomy, fixation of round ligaments (Obhausen). Post-operative diagnosis, same. Complications, none. Discharged Nov 5 relieved. Results May 96 anatomical condition excellent abdominal corrected dysmenorrhea much better.

CASE 11 N. 9875. Age 46. Came for relief of protrusion from vagina, left bearing-down pains. Pre-operative diagnosis, prolapse. Operation, Oct. 27 either Dr W P Graves, amputation of cervix anterior colporrhaphy perineorrhaphy fixation of round ligaments. Post-operative diagnosis same. Complications, none. Discharged Nov 5 relieved. Results June, 96 slight rectocele anatomical result otherwise excellent patient feels much better occasional backache few hot flashes.

CASE 12 N. 9860 Age 46. Came for the relief of menorrhagia. Pre-operative diagnosis, fibroid. Operation, Oct. either Dr W P Graves, supravaginal hysterectomy. Post-operative diagnosis, same. Complications none. Discharged Nov 5 relieved. Results June, 96 anatomical ondition excellent patient feels perfectly all.

CASE 13 N. 95. Age 45. Came for relief of backache profuse leucorrhoea. Pre-operative diagnosis, pelvic inflammation of mass in left side. Operation, Oct. either Dr F A Pemberton supravaginal hysterectomy. Post-operative diagnosis, same. Discharged Nov 5 relieved. Results June, 96 abdominal wound healed slight laceration of perineum and some cystocele patient feels perfectly well except for hot flashes once.

CASE 14 N. 985. Age 5. Came for relief of fertility and dysmenorrhea. Pre-operative diagnosis, infection. Operation Oct. 7, either Dr F A Pemberton dilatation of cervix fixation of round ligaments (Obhausen). Post-operative diagnosis, same. Discharged Nov 5 relieved. Results June, 96 anatomical condition excellent dysmenorrhea greatly relieved.

CASE 15 N. 9864. Age 4. Came for the relief of menorrhagia left pain to left lower quadrant. Pre-operative diagnosis, infection. Operation Oct. 7 either Dr W P Graves dilatation, appendectomy intra-abdominal steming of round ligaments (May). Post-operative diagnosis same. Complications, none. Discharged Nov 5 relieved. Results June, 96 anatomical condition excellent menorrhagia has ceased, patient complains of vaginal and abdominal discomfort no anatomical cause found.

CASE 16 N. 9865 Age 43. Came for relief of painful and bleeding hemorrhoids. Pre-operative diagnosis, lacerated perineum with recto hemorrhoids and fissure in ano. Operation, Oct. 8 either Dr F A Pemberton anterior colporrhaphy perineorrhaphy excision of rectal polyp and hemorrhoids. Post-operative diagnosis same. Complications none. Discharged Nov 5 relieved. Last result June 96 good result from vaginal operation patient much improved little bleeding from hemorrhoids when constipated.

CASE 17 N. 9869 Age 3. Came for relief of retroversion. Pre-operative diagnosis, retroversion-fibroid with prolapse. Operation Oct. 28, either Dr W P Graves, appendectomy fixation of round ligaments (Obhausen). Post-operative diagnosis, same. Complications, none. Discharged Nov 5 relieved. Last result unknown.

CASE 18 N. 9870 Age 53. Came for relief of pressure of tumor on bladder. Pre-operative diagnosis, large abdominal tumor probably fibroid. Operation Oct. 8 either Dr W P Graves supra vaginal hysterectomy excision of cyst. Post-operative diagnosis, large tumor with ovarian cyst (adenocarcinoma of ovary). Complications, none. Discharged Nov 5 relieved. Last result June, 96 anatomical result excellent patient feels perfectly well.

CASE 9. No 9871. Age 46. Came for relief of menorrhagia. Pre-operative diagnosis fibroids post-operative hernia. Operation Oct. 28 either Dr W. P. Graves supravaginal hysterectomy lysis of adhesions radical cure of hernia. Post-operative diagnosis, same pelvic inflammation. Complications none. Discharged Nov. 5. Late result, May 1906 of weakness in left inguinal region anatomical result otherwise excellent patient feels well.

CASE 20. No 9850. Age 38. Came for relief of incontinence of feces backache pain in right side. Pre-operative diagnosis complete laceration of perineum. Operation Oct. 8 either Dr W. P. Graves anterior colpo-rhaphy (Emmett's) perineorrhaphy complete laceration. Post-operative diagnosis, same. Complications none. Discharged Nov. 20 relieved complete control of gas and feces. Late result unknown.

CASE 1. No 9854. Age 37. Came for relief of constant dull ache in left lower quadrant irregular periods. Pre-operative diagnosis, retroversion sterility. Operation Oct. 8 either Dr F. A. Pemberton, right salpingo-oophorectomy fixation of round ligament (Olshausen's) pendency. Post-operative diagnosis retroversion tubal pregnancy. Complications none. Discharged Nov. 5 relieved. Late result June 9 anatomical condition excellent pregnant at month.

CASE 22. No 9855. Age 44. Came for relief of metrorrhagia pain in lower abdomen. Pre-operative diagnosis distasia of recti muscles probable fibroid. Operation Oct. 10 either Dr W. P. Graves supra-pubic hysterectomy pendency approximation of recti muscles. Post-operative diagnosis same hydrosalpinx. Complications none. Discharged Nov. 5 relieved. Late result unknown.

HOUSE OF THE GOOD SAMARITAN

Three Cases

CASE. No 20. Age 9 F. Infantile paralysis flexion of hip. Operation Oct. 18 either Dr Robert Sohier Soutter operation. Complications no diphtheria. Result Aug. 9 6 hips straight patient able to walk with apparatus to keep knees straight the muscles controlling the knee being paralyzed. Patient had not walked before operation for seven years.

CASE. No 2017. Age M. Congenital dislocation of hip. Operation Oct. 27 either Dr James W. Sever reduction of dislocation by Bradford machine. Result Aug. 9 6 hip in place but the leg stiff. Manipulation under ether. Ultimate results to be expected in about nine months from now.

CASE 3. No 2019. Age 8 M. Obstetrical paralysis of right arm. Operation Oct. 8 either Dr James W. Sever myotomy of subscapularis and pectoralis major. Results Aug. 1 9 6 excellent.

LONG ISLAND HOSPITAL

Nine Cases

CASE 1. No 35523. Age 65 F. Fibroid of uterus. Operation Oct. 26 either Dr J. H. Cunningham exploratory. Post-operative diagnosis carcinoma of the uterine body. Complications, none. Discharged Dec. 24 1916 metastatic carcinoma.

CASE. No 35688. Age 63 M. Painful and frequent micturition. Pre-operative diagnosis tumor in bladder hypertrophy of prostate. Operation Oct. 36 either Dr J. H. Cunningham Jr perineal section prostatectomy. Post-operative diagnosis tumor in bladder median prostatic bar. Complications, perineal fistula loss of

vesical control. Discharge 1 1/2 in 24 hours. Late result July 16 partial tumor.

CASE 4. No 3550. Age 48 M. Fibroid of uterus. Operation Oct. 26 either Dr J. H. Cunningham exploratory. Post-operative diagnosis adenoma. Complications slight. Discharge 1 1/2 in 24 hours. Late result July 16 perfect.

CASE 4. No 3500. Age 48 M. Fibroid of uterus. Operation Oct. 26 either Dr J. H. Cunningham perineal section. Complications, slight. Discharge 1 1/2 in 24 hours. Late result July 16 perfect.

CASE 5. No 3500. Age 48 M. Fibroid of uterus. Operation Oct. 26 either Dr J. H. Cunningham perineal section. Complications, slight. Discharge 1 1/2 in 24 hours. Late result July 16 perfect.

CASE 6. No 3500. Age 48 M. Fibroid of uterus. Operation Oct. 26 either Dr J. H. Cunningham perineal section. Complications, slight. Discharge 1 1/2 in 24 hours. Late result July 16 perfect.

CASE 7. No 3500. Age 48 M. Fibroid of uterus. Operation Oct. 26 either Dr J. H. Cunningham perineal section. Complications, slight. Discharge 1 1/2 in 24 hours. Late result July 16 perfect.

CASE 8. No 3500. Age 48 M. Fibroid of uterus. Operation Oct. 26 either Dr J. H. Cunningham perineal section. Complications, slight. Discharge 1 1/2 in 24 hours. Late result July 16 perfect.

CASE 9. No 3500. Age 48 M. Fibroid of uterus. Operation Oct. 26 either Dr J. H. Cunningham perineal section. Complications, slight. Discharge 1 1/2 in 24 hours. Late result July 16 perfect.

MASSACHUSETTS CHARITABLE EYE AND EAR INFIRMARY

Sixty nine Cases
Ophthalmic Service

CASE 1. No 4. Age 4 M. Piece of steel in eye ball. Operation Oct. 5 either Dr W. B. Lancaster removal of foreign body. Complication exudative choroiditis. Discharged Nov. 5 white eye date in childhood shadows projected on face. Result Aug. 1906 perfect.

CASE. No 428. Age 4 F. Tumor of right orbit. Operation Oct. 9 either Dr E. K. Ell. Extirpation of right lachrymal gland. Post-operative diagnosis degeneration of right lachrymal gland. No complications. Discharge Oct. 4.

CASE 3. No 4206. Age 44 M. Came for relief of ectropion of lower lid. Operation Oct. 5 either Dr E. K. Ell. Plastic operation. Snellen's vision N. Complications. Discharged Nov. 9. Result good.

CASE 4. No 408. Age M. Hypermature cataract left. Operation Oct. 5 cocaine. Dr P. H. Thompson combined traction of cataract. No complications. Diabetes. Discharged Nov. 5. Eye white and quiet vision in both glasses 20/40. End result Aug. 1906 eye white and quiet vision with glasses 20/40 +.

CASE 5. No 4220. Age 67 F. Cataract left vs. Operation Oct. 6 cocaine. Dr M. Les. St. John's intra-capsula extraction of cataract by Smith method, slight loss of vitreous. No complications. Discharge Nov. 17 vision 20/20 condition good. End result Aug. 9 6 good no double vision.

CASE 6 No. 4248 Age 3 F Came for relief of phthisis bulbi. Operation, Oct. 28 ether Dr H. B. Stevens, excision with insertion of glass ball. No complications. Discharged Nov 5 condition good.

CASE 7 No. 4306 Age 6 F Senile mature cataract, left. Operation, Oct. 29 cocaine, Dr P. H. Thompson, combined cataract extraction. Complication, slight iritis. Discharged Nov 7 slight injection present, some capsule in pupil vision 1th glass 20/30-40.

CASE 8 No. 4317 Age 75 F Senile mature cataract, left. Operation Oct. 28 holocaine, Dr F. E. Cheney, extraction of cataract with b. Irtetol Iridectomy. Complication, iritis. Discharged Nov 3 vision 20/30 condition not noted.

CASE 9 No. 4314 Age 51 F Staphylococcus of cornea, right. Operation, Oct. 29 ether Dr P. H. Thompson excision with insertion of glass ball. N complications. Discharged Nov condition good.

CASE 10 No. 4344 Age 64 F Senile mature cataract, left. Operation, Oct. 28 holocaine, Dr F. E. Cheney cataract extraction with buttonhole iridectomy. N complications. Discharged condition good. End-result, no date given, eye in good condition vision 1th glass 20/30.

CASE 11 No. 4377 Age 7 F Foreign body left eyeball. Operation Oct. 29 ether Dr W. B. Lancaster removal of foreign body with magnet. N complications. Discharged Nov some injection still vision 20/40.

CASE 12 No. 3988 Age 3 M Prolapsing exophthalmos arteriovenous aneurysm of orbit. Operation, Oct. 7 ether Dr Lincoln Davis, arterial operation several enlarged vessels tied 1 apex of orbit. Complication, whooping cough. Discharged Nov 20 relieved. Result June 19 exophthalmos practically gone no pulsation or bruit vision good not in good internal rotation limited excellent cosmetic result.

CASE 13 No. 4308 Age 13 F Buphthalmos of both eyes. Operation, Oct. 26 ether Dr C. S. Derby pars clementis, anterior chamber left. N complications. Discharged Nov eye white and q. 1 condition same. End result, July 9 6 unchanged condition not relieved.

CASE 14 No. 4355 Age 5 I I tri-ocular tumor right. Operation Oct. 20 novocaine Dr W. B. Lancaster excision. N complications. Post-operative diagnosis, melanotic sarcoma of choroid. Discharged Nov 1 sound healed condition good.

CASE 15 No. 424 Age 9 I Chronic dacryocystitis, left. Operation Oct. ether Dr P. S. Smyth, removal of tear sac. N complications. Discharged Nov 4 sound healed.

CASE 16 No. 4305 Age 75 F Immature cataract right. Operation, Oct. 7 cocaine Dr J. H. Verhoeff cataract extraction in capsule Turok method. Complication, capsule not removed required needling. Discharged Nov 9 somewhat injected good opening in capsule.

CASE 17 No. 3933 Age 40 M Perforating wound right eyeball. Operation Oct. 5 novocaine, Dr W. B. Lancaster excision, right eye. Considerable amount of pain during operation. N complications. Discharged Oct. 30 sound healed.

CASE 18 No. 4243 Age 63, M. Senile mature cataract left. Operation, Oct. 29 cocaine Dr P. H. Thompson, combined cataract extraction. N complications. Discharged Nov 13 eye white and quiet slight membrane in pupil vision 1th glass 20/40-.

CASE 19 No. 3809 Age 60, M. Secondary cataract, right. Operation, Oct. 13, cocaine, Dr P. H. Thompson, needling right. N complications. Discharged Nov 17 eye quiet; vision with glass 20/70.

CASE 20 No. 4246 Age 70 M. Immature cataract, right. Operation Oct. 5 cocaine Dr P. H. Thompson, combined cataract extraction loss of vitreous. N complications. Discharged Nov 20 pupil and media clear; eye white and quiet, vision with glass 20/70. End-result June 29 9 6 pupil drawn up some capsule in pupil vision with glass 20/40.

CASE 21 No. 4309 Age 65 F Immature cataract, right. Operation, Oct. 7, cocaine Dr F. H. Verhoeff combined cataract extraction. N complications. Discharged Nov 9 Condition good. End result condition good vision 1th glass 20/30.

CASE 22 No. 430 Age 53 M Chronic dacryocystitis left. Operation, Oct. 9 ether, Dr P. S. Smyth, excision of left lachrymal sac. N complications. Discharged Nov 1 sound off healed. End-result, no visible slight lachrymation good result.

CASE 23 No. 4337 Age 4 M Pterygium of both eyes. Operation, Oct. 29, cocaine, Dr E. K. Ellis, Mc. Reaoid transplantation operation, both eyes. N complications. Discharged Nov good result. End-result no recurrence of disease.

CASE 24 No. 430 Age 53 M Secondary cataract left. Operation Oct. 29, cocaine, Dr P. H. Thompson needling. N complications. Discharged Nov eye white and quiet. End-result pupil clear vision 1th glass 20/30.

CASE 25 No. 470 Age 53 M. Secondary cataract, right. Operation Oct. 30 cocaine, Dr P. H. Thompson, needling. N complications. Discharged Nov 20 eye white and quiet, vision with glass 20/30. End-result good opening in pupil vision 1th glass 20/40 vision reduced somewhat by small corneal scar.

CASE 26 No. 407 Age 7 M Senile mature cataract right. Operation Oct. 26, cocaine Dr Myers standard combined extraction loss of vitreous. Complications conjunctivitis from trichiasis. Discharged Nov condition good. End-result, clear opening in pupil vision with glass 20/30.

CASE 27 No. 4305 Age 45 F Secondary cataract, right eye. Operation Oct. 8 cocaine Dr P. H. Thompson needling. N complications. Discharged Oct. 30 slight injection good opening in pupil. End-result, good vision with glass 20/30.

CASE 28 No. 4308 Age 3 M Acute glaucoma, right eye following intracapsular extraction of congenital cataract. Operation Oct. 30 Dr Irtetol cataract knife pruned across anterior chamber and through the sclera allowing escape of aqueous. Complication piece of iris carried into incision. Discharged Nov condition good tension normal. End-result, patient has definite filtration scar, tension 8 mm. vision 1th glass 20/30.

CASE 29 No. 4304 Age 50, M Immature senile cataract, left eye. Operation Oct. 28 holocaine, Dr F. E. Cheney combined extraction. N complications. Discharged Nov condition good. End-result good opening in pupil vision with glass 20/30.

CASE 30 No. 433 Age 30 F Subacute glaucoma right eye. Operation, Oct. 5 ether Dr P. H. Thompson, iridectomy right. N complications. Discharged Nov 13 eye white and quiet vision 20/30. End-result, good small tag of iris quiet in wound tension 8 mm. vision with glass 20/70-.

CASE 31 No. 434 Age 67 M. Simple glaucoma, left, tension 70 mm. Operation, Oct. 27 cocaine, Dr De la Harrower Iridotomy. No complications. Discharged Oct. 3 improved. End-result, eye white and quiet, tension norm. filtration scar.

CASE 32 No. 4245 Age 60 M Immature cataract, left. Operation, Oct. 7 cocaine, Dr F. H. Verhoeff

CASE 4. No. 304503. Age 50, F. Rectum protrudes on straining. Pre-operative diagnosis, prolapse of rectum. Operation, Oct. 5, ether and novocaine. Dr. D. F. Jones, rectopexy cul-de-sac closed; rectum sutured to pelvic peritoneum. Complications, none. Discharged Nov. 1, relieved. Result, July 9, 6. Abdominal wound solid; sphincter relaxed, on straining mucosa protrudes about two inches, but no trouble as before but 1 less degree.

CASE 5. No. 304860. Age 51, M. Pain in right abdomen, year slight jaundice, liver enlarged. Echinoscoccus fixation test positive. Pre-operative diagnosis, echinoscoccus cyst of liver. Operation, Oct. 5, ether and novocaine. Dr. D. F. Jones, drainage of echinoscoccus cyst of liver. Post-operative diagnosis, same. Complications, none. Discharged Nov. 30, relieved. Result, July 9, 6. Man in bank discharging pump; patient looked sick, readmitted for further operation.

CASE 6. No. 304937. Age 47, F. Indigestion and epigastric pain for 7 years. Pre-operative diagnosis, gall-stones. Operation, Oct. 5, ether and novocaine. Dr. D. F. Jones, gall-bladder, stomach, pancreas, spleen and kidney seemed normal; appendectomy. Post-operative diagnosis, cholelithiasis, appendicitis. Complications, none. Discharged Nov. 9, relieved. Lat. result, June, 9, 6. Patient complained of exactly same symptoms as before operation: pain in abdomen, back, and tenderness in gall-bladder region. Recommended for re-admission. Letter from patient, Aug. 9, 6, "feeling better, too busy" to enter hospital at present.

CASE 7. N. 30487. Age 7, F. Vomiting and epigastric pain 3 months, loss of weight, tumor. Pre-operative diagnosis, carcinoma of stomach. Operation, Oct. 26, ether. Dr. C. A. Porter, partial gastrectomy, anterior gastro-enterostomy. Post-operative diagnosis, same. Complications, none. Discharged Nov. 30, relieved. Lat. result, July 9, 6, greatly improved after operation for 7 months; during last month pain and loss of weight. Re-admitted probably recurrence; mass also of lemon in right epigastrium attached to liver. Further operation not desired.

CASE 8. No. 30483. Age 64, F. Tumor of neck for 47 years. Pre-operative diagnosis, cystic goiter. Operation, Oct. 26, gas and oxygen and novocaine. Dr. G. W. W. Brewster, removal of right lobe of thyroid. Post-operative diagnosis, same. Complications, none. Discharged Nov. 5, relieved. Result, July 9, 6, better; feels much better; working; thinks operation a success.

CASE 9. N. 30488. Age 4, F. Pain in back. Irregular menstruation, bladder irritation. Pre-operative diagnosis, myoma of uterus. Operation, Oct. 26, gas and ether. Dr. G. W. W. Brewster, cyst of broad ligament removed; appendectomy. Post-operative diagnosis, cyst of left broad ligament. Complications, none. Discharged Nov. 9, relieved. Result, July 9, 6, wound solid; no complaints; working.

CASE 10. No. 304904. Age 50, M. Fracture of patella, 4 days duration. Pre-operative diagnosis, same. Operation, Oct. 26, ether. Dr. C. L. Scudder, open reduction and suture. Post-operative diagnosis, same. Complications, none. Discharged Nov. 14, relieved on crutches. Result, July, 9, 6, bony union; flexion to beyond right angle; extension normal, 2 times up on walking; has not worked since leaving hospital (painter).

CASE 11. N. 30480. Age 30, F. Pain in right upper quadrant, vomiting, tenderness. Pre-operative diagnosis, cholelithiasis. Operation, Oct. 26, ether. Dr. G. W. W. Brewster, cholecystectomy; gall-bladder filled with soft stones. Post-operative diagnosis, same. Complications, none. Discharged Nov. 18, relieved. Result, July 9, 6, wound solid; patient well in every respect, working.

CASE 12. No. 304753. Age 47, F. Indigestion for years, pain and vomiting for three weeks, hematemesis. Pre-operative diagnosis, cholelithiasis or duodenal ulcer. Operation, Oct. 26, ether. Dr. G. W. W. Brewster, posterior gastro-enterostomy with infolding for duodenal ulcer; appendectomy. Post-operative diagnosis, duodenal ulcer; gall-bladder normal. Complications, none. Discharged Nov. 4, relieved. Result, July 9, 6, wound solid; feels and looks well, has gained weight; no gastric symptoms.

CASE 13. N. 304878. Age 3, M. Pre-operative diagnosis, ununited fracture neck of femur. Operation, Oct. 5, ether. Dr. C. L. Scudder, bone-peg from tibia inserted into neck of femur; plaster. Post-operative diagnosis, same. Complications, none. Discharged Dec. 7, relieved on plaster. Lat. result, bone-peg accidentally fractured while changing plaster, Feb. 9, 6. Result, June, 9, 6, no plaster; position excellent; can flex thigh on trunk; motions somewhat restricted, not yet bearing full weight on thigh.

CASE 14. N. 304908. Age 4, F. Tumor of breast, 1 year's duration. Pre-operative diagnosis, fibrocystic disease. Operation, Oct. 7, gas and ether. Dr. G. W. W. Brewster, subcutaneous incision of breast. Post-operative diagnosis, pendulous fibroma. Complications, none. Discharged Nov. 5, relieved. Result, July 9, 6, patient reports by letter general health greatly improved.

CASE 15. N. 304905. Age 50, F. Indigestion and attacks of pain in right and left abdomen. Pre-operative diagnosis, gall-stones. Operation, Oct. 7, gas and ether. Dr. G. W. W. Brewster, cholecystectomy. Post-operative diagnosis, same. Complications, none. Discharged Nov. 9, relieved. Result, July 9, 6, wound solid; complains of same discomfort as before operation; heartburn, burp, flatulency.

CASE 16. N. 304950. Age 6, M. Frequent urination, one attack of retention. Pre-operative diagnosis, hypertrophied prostate. Operation, Oct. 7, spinal anesthesia, Dr. Franklin G. Balch, perineal prostatectomy. Post-operative diagnosis, same. Complications, none. Discharged Nov. 9, relieved. Result, July 9, 6, general condition excellent; voids solid; working; no urinary symptoms; urine clear; no residual.

CASE 17. N. 304945. Age 40, M. Pre-operative diagnosis, epigastric hernia. Operation, Oct. 7, ether. Dr. Franklin G. Balch, closure of epigastric hernia. Complications, none. Discharged Nov. 9, relieved. Result, July 9, 6, wound solid; no symptoms; working.

CASE 18. No. 304870. Age 50, F. Large abdominal tumor. Pre-operative diagnosis, ovarian cyst. Operation, Oct. 7, ether. Dr. Franklin G. Balch, cyst tapped and removed. Post-operative diagnosis, same. Complications, none. Discharged Nov. 8, relieved. Result, July 9, 6, better; reports health excellent.

CASE 19. N. 30498. Age 30, F. Nodule in breast 4 months duration. Pre-operative diagnosis, carcinoma of breast. Operation, Oct. 7, Dr. Samuel J. Miter, removal of breast and pectorals, and dissection of axilla, closure of wound by "cyclops" plastic. Post-operative diagnosis, same. Complications, none. Discharged Nov. 8, relieved. Result, July 9, 6, wound well healed, no evidences of recurrence; motions of arm free; excellent health; doing housework.

CASE 20. N. 304983. Age 30, F. Sharp pain in right upper abdomen for 2 weeks, jaundice. Pre-operative diagnosis, gall-stones. Operation, Oct. 7, ether. Dr. S. J. Miter, cholecystectomy. New-growth involving gall-bladder and head of pancreas. Post-operative diagnosis, adenocarcinoma of biliary passages. Complications, none. Discharged Nov. 9, unrelieved. Late result, letter states patient died about Dec. 20, 9, 5.

CASE 20 No 204971 Age 61 M Pain tenderness and muscle spasm over gall bladder region. Pre-operative diagnosis cholecystitis. Operation Oct. gas and ether Dr G W W Brewster cholecystostomy many ates removed Post-operative diagnosis same with hotel. Complications none Discharged Nov. 10. Relieved. Result July 1916 wound solid d t n excellent work slight epigastric discomfort at times.

CASE 21 No 204972 Age 5 F Abdominal tumor year lost 43 pounds in weight omitting Pre-operative diagnosis myoma of uterus. Operation Oct. ether Dr G W W Brewster supra-umbilical hysterectomy double salpingo-oophorectomy Post-operative diagnosis, cysto-adenoma of uterus and ovary Discharged Nov. 10. Relieved. Re-entered hospital Dec. 10 with gastric distress and vomiting Operation by Dr C W W Brewster abdominal extensive carcinoma at p l r u s. After gastro-enterostomy done Discharged July 1916. Relief of symptoms for a few weeks. Patient died March 13 1916.

CASE 22 No 204957 Age 42 F Umbilical tumor 10 years duration. Pre-operative diagnosis same. Operation Oct. 7 ether Dr Farrar Cobb lipectom closure of umbilical hernia (Mayo) Post-operative diagnosis same. Complications none. Discharged Nov. 9. Relieved. Result July 9 1916 wound solid feel well and strong work long.

CASE 23 No 204846 Age 45 M Ulcerated tumor of lip 3 years duration. Operation on lip 8 years pre-operative diagnosis, epithelioma. Operation Oct. 27 Dr Farrar Cobb removal of lower lip with cautery knife dissection of neck plastic. Complications none separation of wound edges. Discharged Nov. 10. Relieved. Later result re-entered Jan. 2 1916 small plastic operation on lip for deformity. Evidence of recurrence subsequent history not known.

CASE 24 No 204973 Age 4 F Abdominal pain and menorrhagia. Pre-operative diagnosis menometrorrhagia. Operation Oct. 2 ether Dr Farrar Cobb supra-umbilical hysterectomy double salpingo-oophorectomy Post-operative diagnosis, same. Complications pleurisy operation Oct. 28 to question if post-operative hemorrhage none found Post-operative psychosis Discharged November 3. Relieved. Result July 9 1916 wound solid some leucorrhoea feels strong able to do housework very nervous.

CASE 25 No 20496 Age 0 F Hematuria and pain for 1 month. Pre-operative diagnosis renal calculus. Operation, Oct. 7 ether Dr Lincoln Davis nephrectomy Post-operative diagnosis, pyelonephrosis with renal stone. Complications none. Discharged Nov. 5. Relieved. Result, July 9 1916 wound solid fine cloudy feel well no symptoms of any kind working 9 hours a day.

CASE 26 No 204947 Age 34 F Tumor of abdomen 6 months duration. Pre-operative diagnosis ovarian cyst. Operation, Oct. 7 ether Dr Lincoln Davis excision of ovarian cyst supra-umbilical hysterectomy double salpingo-oophorectomy Post-operative diagnosis, ovarian cyst and myoma of uterus. Complications none. Discharged Nov. 10. Relieved. Result July 9 1916 wound solid general condition excellent trouble at first with hot flashes, much improved now doing housework.

CASE 27 No 204849 Age 5 I Pain in right lower abdomen with tenderness for 8 weeks. Pre-operative diagnosis chronic appendicitis. Operation Oct. 7 ether Dr Farrar Cobb appendectomy Post-operative diagnosis same. Complications none. Discharged Nov. 1. Relieved. Late in July 9 1916 no pain digestion or mal wound solid health excellent.

CASE 28 No 204555 Age 0 M Right side of urine. Pre-operative diagnosis, hemiplegia. Operation Oct. 10 ether Dr Lincoln Davis Balh penicillin. Post-operative diagnosis, same. Discharged Nov. 10. Relieved. Result July 9 1916 wound solid feel well no symptoms of any kind working 9 hours a day.

CASE 29 No 204555 Age 0 M Right side of urine. Pre-operative diagnosis, hemiplegia. Operation Oct. 10 ether Dr Lincoln Davis Balh penicillin. Post-operative diagnosis, same. Discharged Nov. 10. Relieved. Result July 9 1916 wound solid feel well no symptoms of any kind working 9 hours a day.

CASE 30 No 204555 Age 0 M Right side of urine. Pre-operative diagnosis, hemiplegia. Operation Oct. 10 ether Dr Lincoln Davis Balh penicillin. Post-operative diagnosis, same. Discharged Nov. 10. Relieved. Result July 9 1916 wound solid feel well no symptoms of any kind working 9 hours a day.

CASE 31 No 204555 Age 0 M Right side of urine. Pre-operative diagnosis, hemiplegia. Operation Oct. 10 ether Dr Lincoln Davis Balh penicillin. Post-operative diagnosis, same. Discharged Nov. 10. Relieved. Result July 9 1916 wound solid feel well no symptoms of any kind working 9 hours a day.

CASE 32 No 204555 Age 0 M Indigestion and epigastric pain 4 years omitting emetic. Pre-operative diagnosis, indigestion. Operation Oct. 20 ether Dr C L Scudder pyloroplasty. Post-operative diagnosis, same. Discharged Nov. 10. Relieved. Result July 9 1916 wound solid feel well no symptoms of any kind working 9 hours a day.

CASE 33 No 2049 Age 45 M Pain in epigastrium in retracted tummy food tastes like porridge. Diagnosis, tumor of pylorus. Operation Oct. 20 ether Dr C L Scudder pyloroplasty. Post-operative diagnosis, same. Discharged Nov. 10. Relieved. Result July 9 1916 wound solid feel well no symptoms of any kind working 9 hours a day.

CASE 34 No 20490 Age 54 F Tumor of right side of neck slight exophthalmos and shortness of breath. Left side of the body emaciated months ago by Dr C A Port. Pre-operative diagnosis, collared goiter. Operation Nov. 10 ether Dr C A Port. Right lobe of thyroid removed. Post-operative diagnosis, same. Complications none. Discharged Nov. 10. Relieved. Result July 1916 excellent sea food well good result.

CASE 35 No 204936 Age 3 M Faral from fall ing accident 5 months ago. Pre-operative diagnosis, ruptured brachial plexus. Operation Oct. 7 ether Dr C A Port. Plevex fund and nerve suture. Post-operative diagnosis, same. Complications none. Discharged Nov. 9. Relieved. Result, July 9 1916 clavical united in return of function in nerves muscle laryngeal paralysis hyperaesthesia fulva and median supply.

CASE 37 No. 20403 Age 14, M Pre-operative diagnosis, undescended testicle. Operation, Oct. 29, Dr D. F. Jones, Bessie operation closure of hernia. Post-operative diagnosis, same, plus inguinal hernia. Complications, none. Discharged Nov. 3 relieved. Result, July 9 6 wound solid testicle well d. in scrotum, same size as left no subjective symptoms.

CASE 38 No. 20409 Age 3 M Old tuberculous of knee, ankylosis at 90°. Pre-operative diagnosis, same. Operation, Oct. 29 either Dr D. F. Jones amputation of knee-joint. Post-operative diagnosis, same. Complications, hematoma with separation of wound edges. Discharged Nov. 3 relieved. Lat. result, readmitted Nov. 3, 9 5 for hematoma and separation of flaps. Result, July 9 6 wound solid good stump wearing artificial leg; working in machine shop no pain.

CASE 39 No. 20434 Age 8 F Pal nausea diarrhoea loss of weight. Appendectomy and oophorectomy years ago. Pre-operative diagnosis, colitis. Operation, Oct. 29 gas and vygon, and novocaine, D. F. Jones lateral anastomosis of ileum to transverse colon. Post-operative diagnosis, tuberculosis of colon. Complications, none. Discharged Nov. 10 relieved. Result, July 9 6 wound solid creases palpable slight signs 1 lumps no pain, diarrhoea, or nausea, gained 44 pounds up to months ago since then has lost eight some cough for months.

CASE 40 No. 20454 Age 4 M Pre-operative diagnosis, peritonitis aemia. Operation, Oct. 29, either Dr B. H. Vincent, splenectomy. Post-operative diagnosis, same. Complications, transfused on second day after operation, wound broke open on fifth day resutured. Discharged Nov. 20, relieved. Result, July 9 6 wound solid improved steadily up to March, was 1 work when suddenly began to get worse transfused twice by Dr Vincent recently unable to work hard, 55% red count 750,000.

CASE 41 N 20493 Age 26 F Swelling of neck some palpitation, dyspnea and tremor pulse 80. Pre-operative diagnosis, colloid goiter slightly toxic. Operation, Oct. 29 gas and either D. C. A. Porter greater portion of both lobes removed. Complications, slight sepsis. Discharged Nov. 7 relieved. Went to Ireland letter received by sister July 9 6 (late patient is in excellent health).

CASE 42 N 20490 Age 75 M Papillary mass on tip and inside of cheek, years duration. Pre-operative diagnosis, epithelioma. Operation (lat. 29) either Dr R. B. Greenough excision of growth dissection of neck. Complications, none. Discharged Nov. 7 relieved. Letter from patient Aug. 9 6 states health excellent no recurrence month rather small.

CASE 43 N 20495 Age 1 M Oblique fracture of femur. Pre-operative diagnosis, same. Operation Oct. 29 either Dr R. B. Greenough, incision reduction, Parham band applied plaster. Complications, none. Discharged Nov. 24 relieved 1 plaster R admitted Feb. 9 6 band removed. Result, June 9 6 no shortening walked with slight limp moderate trophy of thigh still present. Aug. 9 6 seen b. Dr Greenough leg one-quarter inch longer than the other no limp no trophy of thigh does everything that other boys do.

CASE 44 No. 20496 Age 45 M Large tumor of buttock, 4 months. Pre-operative diagnosis, fibrosarcoma of buttock. Operation, Oct. 29 either Dr R. B. Greenough, tumor excised. Post-operative diagnosis, same. Complications, none. Discharged Nov. 9, relieved. Result March 9 6 died of recurrence: 4 Cooley treatments at Haddington Hospital.

CASE 45 N 20495. Age 47 F Lump in right breast for one year. Pre-operative diagnosis, carcinoma. Operation, Oct. 29, either Dr R. B. Greenough, dissection of axilla removal of breast 1th pectoralis. Post-operative diagnosis, same. Complications, granulating wound, erysipelas. Discharged Dec. 9 relieved. Thiersch graft Dec. 8. Result Aug. 10 6 letter from patient states that she is doing her own housework, can arm pretty well health good has gained 30 pounds examination negative.

Gentle-I is any Service

CASE 46 N 20498 Age 46 M Intermittent hematuria. Pre-operative diagnosis, papilloma of bladder. Operation Oct. 5 gas and oxygen, Dr Hugh Cabot, suprapubic cystotomy, excision of tumor. Post-operative diagnosis, same. Complications, none. Discharged Dec. 3, relieved. Result, July 9 6 wound solid, urine cloud, slight frequency and burning: cystoscopy shows no evidence of recurrence.

CASE 47 N 20499 Age 7 M Vesical calculus. Operation, Oct. 5 gas and vygon Dr Hugh Cabot, lithotomy. Post-operative diagnosis, same. Complications, none. Discharged Oct. 8 relieved. Result, July 9 6 daughter report patient too busy to come in "seems in good health."

CASE 48 N 20495 Age 68 M Frequent micturition and dribbling. Pre-operative diagnosis, hypertrophied prostate. Operation, Oct. 5 gas and oxygen, Dr R. F. O'Neil suprapubic prostatectomy. Complications, none. Discharged Nov. 7 relieved. Result, July 9 6 feels well gained weight was incontinent for some months, now has very slight incontinence, goes 1 night to 1 three times double inguinal hernia, urine cloudy residual 5 drams.

CASE 49 No. 20495 Age 20 M Swelling of testicle. Pre-operative diagnosis, testicular epididymitis. Operation Oct. 5 gas and oxygen, Dr J. D. Barney epididymo-vasectomy. Post-operative diagnosis, chronic inflammation. Complications, none. Discharged Oct. 20 relieved. Result, Aug. 9 6 wound healed testicle feels normal urine clear no local symptoms is being treated with tuberculin.

CASE 50 No. 20497 Age 48 F Pre-operative diagnosis, suppurative infection of left kidney: perinephric abscess. Operation, Oct. 28 Dr Hugh Cabot, nephrectomy. Post-operative diagnosis, perinephric abscess tuberculosis of kidney. Complications, infection of wound. Discharged Dec. 3 relieved. Result June 9 6 improvement in general health, pounds gain in weight wound still discharging no urinary symptoms.

CASE 51 N 20499 Age 8 M Frequent and painful micturition too pain in right flank. Pre-operative diagnosis, tuberculosis of right kidney. Operation Oct. 5 gas and vygon Dr R. F. O'Neil nephrectomy. Post-operative diagnosis, same. Complications, none. Discharged Nov. 9, relieved. Result, July 9 6 reports be letter gained 5 to 10 pounds wound solid urine clear apparently cured.

CASE 52 No. 20499 Age 29 M Pre-operative diagnosis, multiple calculi of right kidney. Operation Oct. 28 gas and oxygen, Dr E. L. Young, J. subcapsular nephrectomy. Post-operative diagnosis, calculus pyonephrosis. Complications, none. Discharged Nov. 16 relieved. Result, July 9 6 wound solid urine clear X-ray negative, feels well, working; some pain in other side.

CASE 53 N 20499 Age 66 M Retention of urine. Pre-operative diagnosis, obstructing prostatic. Operation Oct. 8 local anesthetic, Dr E. C. Crabtree, suprapubic puncture. Post-operative diagnosis, same.

Operation Nov 9, Dr O'Neill suprapubic prostatectomy. Unsuccessful convalescence except for low mental condition. Result, July 1916, report from Dr Kling urine still a little dirty but is improving no trouble with wound or with urination.

Othopedic Service

CASE 54 No 203840 Age 6 M Pain in left hip, 7 years duration. Pre-operative diagnosis by peritrophic arthritis of hip. Operation Oct 6 thru Dr F G Brackett, hip-joint opened, bony overgrowth and cartilage removed, plaster applied. Post-operative diagnosis same. Complications none. Discharged Jan 6 relieved in plaster. Result July 1916 patient in excellent health, wound healed, complete ankylosis of hip-joint, no pain or tenderness, some difficulty in sitting down.

CASE 55 No 01955 Age 25 F Pain in left knee for 11 years swelling and stiffness for 5 years. Pre-operative diagnosis tuberculosis of knee. Operation Oct. 26 ether, Dr E. G. Brackett, joint opened and in expected injection of Iodoform oil. Post-operative diagnosis same. Complications none. Discharged. Nos relieved. Late result, did well at first, Jan 9 discharged sinus advised to re-enter hospital patient refused and is being treated elsewhere.

CASE 56 No 203875 Age 3 M Pain swelling and flexion deformity of knee for 3 years. Arthrotomy and oil injection 2 1/2 years ago, now has instability of joint. Pre-operative diagnosis tuberculous. Operation Oct. 26 gas and ether Dr R B Osgood extension of knee joint fragments held by bone plates. Post-operative diagnosis same. Complications none. Discharged Nov. 19 relieved. Result, July 1916 knee ankylosed in good position, six weeks ago bone-plates removed, small granulating wounds on each side of knee, walks with cane, no pain.

CASE 57 No 203926 Age 33 M Occasional locking of joint, finally inability to move it. Pre-operative diagnosis, loose body in knee joint. Operation Oct. 9 ether, Dr E G Brackett joint opened by long incision splitting of patella, two loose bodies removed. Post-operative diagnosis, osteochondritis desiccans. Complications, tonsillitis. Discharged Nov. relieved in plaster. Result Jun. 1916 wound well healed patella movable flexion practically complete, knee is strong and causes little pain never locks as before operation good result.

CASE 58 No 203738 Age 3 F Limp since 2 years old. Pre-operative diagnosis congenital dislocation of hip. Operation Oct. 28 ether Dr E G Brackett open reduction of dislocation, suture and plaster applied. Post-operative diagnosis, same. Complications none. Discharged, Dec. 6 relieved in plaster. Result Jun. 1916 X-ray shows new acetabulum, limping motions fairly free, light limp and deformity definitely improved by operation.

CASE 59 No 204867 M Intermittent locking of knee. Pre-operative diagnosis dislocated semilunar cartilage. Operation Oct. 3 gas and ether Dr R B Osgood internal semilunar excised. Post-operative diagnosis, same. Complications none. Discharged relieved. Result, Aug. 5 1916 working knee as good as ever, no pain, limitation of motion or locking.

Throat Department

There were 13 operations for removal of tonsils and adenoids, performed by Drs. H A Barnes, J P Clark, D C Greene, J E W Herman, W F Knowles and Chandler R. Boies, under gas and ether anesthesia. The only complication was hemorrhage in one case controlled by suture of pillars. All were discharged relieved. Lat-

result obtained in cases which were satisfactory with the exception that in one case the patient was re-gelatinized. There was no acute abscess, infection or suppuration. There was no marked improvement in the treatment of 1 month without treatment.

There were 5 cases of deviated nasal septum operated upon by Dr Barnes, all under ether anesthesia. In one case the middle turbinate was removed. All cases discharged, relieved, late result known in cases not followed later.

On the 1st of March in past 11 months 11 patients under local anesthesia were performed by Dr C. C. Ten J. It is to be noted that Dr. C. C. Ten J.

Two cases of epiglottitis treated by Dr Barnes and Ten J. under local anesthesia were discharged relieved. Late result known in one case, no further trouble.

MASSACHUSETTS HOMEOPATHIC HOSPITAL

Eighty-four Cases

SALES

CASE No 80 Age 7 F Tumor left breast. Pre-operative diagnosis, carcinoma. Operation Oct. 5 ether Dr William I. Weselhoeft amputation of breast. Post-operative diagnosis same. Complications none. Discharged Nov. 6 relieved. Late result July 9, 1916 wound entirely healed, although an abscess formed after discharge from hospital, patient complains of more or less constant pain in the region of the scar.

CASE No 86 Age 60 M Indigestion, heart burn and milking of stools for years. Pre-operative diagnosis, gastric ulcer. Operation Oct. 5 ether Dr William I. Weselhoeft, esotomy with posterior gastrostomy. Post-operative diagnosis same. Complications, pneumonia. Discharged Nov. 10 dead. Autopsy acute bacterial pneumonia post-operative hypertrophy, chronic gastritis, bronchitis.

CASE No 868 Age 55 F Pain in right hypochondrium and vomiting. Pre-operative diagnosis, cholelithiasis. Operation Oct. 5 ether Dr Thomas E. Chandler, cholecystectomy. Tumor removed. Post-operative diagnosis same. Complications none. Discharged Nov. 5 relieved. Late result June 9, 1916 family physician reports patient relieved of all symptoms.

CASE No 911 Age 58 F Recurrent attacks of pain in lower right abdomen, flatulence and vomiting. Pre-operative diagnosis, appendicitis. Operation Oct. 25 ether Dr Thomas E. Chandler, appendectomy. Post-operative diagnosis same. Complications none. Discharged Nov. 3 relieved. Late result June 9, 1916 wound well gained, twenty pounds, mild attack of acute indigestion, relieved by peristaltic pump.

CASE No 830 Age 2 F Pain epigastrium, chills, fever and vomiting. Tenderness in right inguinal region. Pre-operative diagnosis, appendicitis complicating pregnancy. Operation Oct. 5 ether Dr H. H. Packard, appendectomy. Post-operative diagnosis same. Complications, mild suppuration of wound. Discharged Nov. 3 relieved. Late result could not be traced.

CASE No 826 Age 43 F Menorrhagia, abundant menses reaching umbilicus, frequent micturition and pressure symptoms. Pre-operative diagnosis, fibromyoma of uterus. Operation Oct. 6 gas and oxygen Dr Horace Packard, supra-umbilical hysterectomy. Post-operative diagnosis same. Complications none. Discharged Nov. 10 relieved. Late result could not be traced.

SURGERY GYNECOLOGY AND OBSTETRICS

CASE 7 No. 839 Age 37 F Menorrhagia mass protruding from vulva. Pre-operative diagnosis, fibroma of cervix uteri. Operation, Oct 26 either D J Emmens Briggs vaginal myomectomy. Patient four and one-half month pregnant. Post-operative diagnosis, none. Complications, none. Discharged Nov 5 health baby March 30 916 health perfect.

CASE 8 N 8745 Age 40 F Abdominal pain, right side sore on pressure. Pre-operative diagnosis, appendicitis. Operation Oct 26 either D J Emmens Briggs appendectomy. Post-operative diagnosis, none. Complications slight phlebitis. Discharged Nov 24, relieved. Late result, June 6 condition of wound excellent, troubled by swelling of right leg below of wound three months this difficulty now passing away and gives her but slight inconvenience.

CASE 9. No. 835 Age 55 F Inability to swallow 36 either D J Emmens Briggs dilatation of esophagus and insertion of cannula. Post-operative diagnosis, none. Complications, none. Discharged Dec 4 relieved necessary to introduce another cannula in 11 not healed from above.

CASE 10. No. 876 Age 35 F Frequent profuse hemorrhage during pregnancy. Pre-operative diagnosis, placenta previa. Operation, Oct 26 gas and oxygen, D Charles T Howard, cesarean section. Post-operative diagnosis, same. Complications, none. Discharged Nov 30, relieved. Late result, June 9 condition reported by family physician as perfect.

CASE 11 N 8600 Age 33 F Indefinite abdominal pain, irregular vomiting, constipation. Pre-operative diagnosis, gastro-enteroplegic, appendicitis. Operation, appendectomy. Post-operative diagnosis, same. Complications, none. Discharged Nov 7 relieved. Late result, June 9 6, good result as regards operation constipation and digestive symptoms much improved. Patient has developed, however, sacro-lumbar strain since going home.

CASE 12 N 8746 Age 9 F Pain attack of vomiting without relation to eating constipation. Pre-operative diagnosis, gastro-enteroplegic, nephropathy. Operation, Oct 25 either Dr Charles T Howard, Coffey operation, nephropathy. Post-operative diagnosis, same. Complications, none. Discharged Nov 7 relieved. Late result, June 9 6 stomach and kidney in position much improved in general condition still complaint of dragging sensation in her bowels.

CASE 13 N 8740 Age 3 M Sudden pain in right groin. Pre-operative diagnosis, right inguinal hernia. Operation, Oct 7 either Dr William F Woodcock closure of inguinal hernia. Post-operative diagnosis, same. Complications, none. Discharged Nov 4, relieved. Late result, July 9 6 wound sound no discharge or pain.

CASE 14 N 8505 Age 3 M Hematemesis two years' duration anemia. Pre-operative diagnosis, gastric ulcer. Operation, Oct 7 either Dr W F Woodcock posterior gastro-enterostomy. Post-operative

diagnosis, same. Complications, none. Discharged Nov 5, relieved. Late result, July 9 6 wound solid digestion much improved has gained weight.

CASE 15 N 8745 Age 36 M Right inguinal hernia. Operation Oct 26 either Dr W F Woodcock, Bassini operation of hernia. Post-operative diagnosis, same. Complications, none. Discharged Nov 5, relieved. Late result, July 9 6 wound strong no pain or discomfort never felt no strain.

CASE 16 N 8745 Age 9 F Pain in right side of abdomen on constipation. Pre-operative diagnosis, acute appendicitis. Operation, Oct 26 either D J Emmens Briggs appendectomy. Post-operative diagnosis, same. Complications, none. Discharged Nov 5, relieved. Late result, June 9 6 wound sound health much improved.

CASE 17 N 8745 Age 30 F Pain in right side of abdomen on constipation. Pre-operative diagnosis, right partial ileus. Operation, Oct 26 either D J Emmens Briggs double salpingectomy oophorectomy. Post-operative diagnosis, same. Complications, none. Discharged Nov 5, relieved. Late result, June 9 6 wound firm health

CASE 18 N 8745 Age 5 F Pain and soreness over bony surface and contusion. Pre-operative diagnosis, ventral hernia incarcerated. Operation, Oct 26 either D J Emmens Briggs repair of ventral hernia not lar deposits in abdomen. Post-operative diagnosis, same. Complications, none. Discharged Nov 5, relieved. Late result, June 9 6 patient gradually failed and died of carcinoma, Dec. 10

CASE 19 N 8745 Age 4 M Pain in lumbar region for three years chill and fever. Pre-operative diagnosis, nephropathy. Operation, Oct 26 either Dr J Emmens Briggs, nephropathy. Post-operative diagnosis, same. Complications, none. Discharged Nov 5, relieved. Late result, June 9 6 entire relieved of symptoms general health much improved.

CASE 20 N 8745 Age 41 F Constant pain in epigastrium, none on eating no vomiting no jaundice. Pre-operative diagnosis, adhesions. Operation, Oct 26 either D J Emmens Briggs, adhesions. Post-operative diagnosis, same. Complications, none. Discharged Nov 5, relieved. Late result, June 9 6 patient writes she is in

CASE 21 N 8745 Age 3 F Dysmenorrhea and menorrhagia. Pre-operative diagnosis, fibroid of uterus. Operation, Oct 26 either Dr George R. Southwick supravaginal hysterectomy. Post-operative diagnosis, same. Complications, none. Discharged Nov 5, relieved. Late result, June 9 6 patient writes she is in

CASE 22 N 8767 Age 35 F Profuse menstrual flow. Pre-operative diagnosis, lacerated perineum. Operation, Oct 26 either Dr George R. Southwick perineorrhaphy. Post-operative diagnosis, same. Complications, none. Discharged Nov 5, relieved. Late result, June 9 6 patient writes she is in

CASE 23 N 8745 Age 37 F Profuse menstrual flow. Pre-operative diagnosis, fibromyoma of uterus. Operation, Oct 26 either Dr George R. Southwick supravaginal hysterectomy. Post-operative diagnosis, same. Complications, none. Discharged Nov 5, relieved. Late result, June 9 6 patient writes she is feeling fine.

morphine ether D. Mary A. Smith D. & C. double salpingectomy appendectomy cholecystostomy excision of hemorrhoids. Post-operative diagnosis, same plus cholecystitis, with gall stones. Complication, infection of skin wound. Discharged Dec. 5 relieved. Result July 1916, abdominal wounds in good condition with posterior dysmenorrhea and backache, defecation painful.

CASE 3 No. 220 Age 27 F Abdominal pain Pre-operative diagnosis ovaritis fibrom. uterus possible appendicitis. Operation Oct. 26 scopolamine morphine ether Dr. Elizabeth Gray D. & C. left oophorectomy myomectomy appendectomy. Post-operative diagnosis same. Complications, none. Discharged Nov. 4 relieved. Patient could not be traced for late result.

CASE 4 No. Ag. 30 F Abdominal pain keloid in scar of previous operation. Pre-operative diagnosis endometritis ante flexion adhesions at splenic flexure keloid scar. Operation Oct. 26 scopolamine morphine only Dr. Emma B. Culbertson D. & C. insertion of Outebridge pessary, excision of keloid lysis of adhesions of splenic flexure of colon puncture of cysts. Post-operative diagnosis same. Complications none. Discharged Nov. 14 relieved. Result July 1916 wound solid. Patient now 4 months pregnant still complains of pain in region of splenic flexure.

CASE 5 No. 227 Age 30 F Pain in right de metrorrhagia sterility. Pre-operative diagnosis ovaritis adhesions of sigmoid. Operation, Oct. 7 scopolamine morphine, ether D. Emma B. Culbertson D. & C. left oophorectomy lysis of adhesions. Post-operative diagnosis same. Complications none. Discharged Nov. 4 relieved. Result August 96 uterus in good position—general health good.

CASE 6 No. 26 Age 47 F Proctitis compl. to Operati. N Oct. 7 scopolamine morphine ether D. Florence Duckering vaginal hysterectomy anterior colporrhaphy penneorrhaphy. Post-operative diagnosis same. Complications, none. Discharged Nov. 4 relieved. Result July 1916 good perineal body in recurrence of symptoms.

CASE 7 No. 31 Age 4 M Oblique fracture of femur Operation Oct. 7 ether Dr. Mary A. Smith reduction by manipulation splints and extension. Complications none. Discharged Nov. 9 relieved. Result July 96 perfect function no shortening no apparent abnormality. Ray shows union with some anterior deformity due to boxing.

CASE 8 No. 2 Age 9 F Ventral hernia chronic oophoritis chronic appendicitis. Operation Oct. 8 scopolamine-morphine, ether Dr. Mary A. Smith appendectomy right salpingo oophorectomy repair of hernia. Post-operative diagnosis same. Complications none. Discharged Nov. 14 relieved. Result Aug. 96 abdominal scar in good condition patient general health satisfactory ray sympt. none elevated.

CASE 9 No. 37 Age 59 F Polyp feces umbilical hernia. Operation Oct. 8 scopolamine morphine only Dr. Mary A. Smith repair of umbilical hernia removal of cervical polyp. Complications none. Discharged Nov. 3 relieved. Examined Aug. 96 no return of umbilical hernia very small scar no return of polyp no vaginal discharge. Very good result patient feeling very well since operation.

CASE No. 4 Age 28 F Backache and bearing down pain. Pre-operative diagnosis lacerated cervix and perineum ectoed. Operation Oct. 8 scopolamine morphine ether Dr. Florence W. D. Kering D. & C. amputation of cervix perineorrhaphy. Complications none. Discharged Nov. 16 relieved. Patient could not be traced for late result.

CASE No. 3 Age 35 F Flank pain Pre-operative diagnosis lacerated cervix and perineum. Operation Oct. 29 scopolamine morphine ether Dr. Mary A. Smith D. & C. amputation of cervix perineorrhaphy. Complications none. Discharged Nov. 16 relieved. Examined Aug. 96 no return of umbilical hernia very small scar no return of polyp no vaginal discharge. Very good result patient feeling very well since operation.

CASE No. 9 Age 34 F Complicated pregnancy. Operation Oct. 9 scopolamine morphine ether Dr. Emma B. Culbertson repair of lacerated cervix lysis of adhesions of sigmoid. Post-operative diagnosis same. Complications none. Discharged Nov. 4 relieved. Result July 1916 wound solid. Patient now 4 months pregnant still complains of pain in region of splenic flexure.

CASE No. 34 Age 60 F Pelvic pain Pre-operative diagnosis salpingitis. Operation Oct. 5 ether Dr. J. W. Lane salpingectomy. Post-operative diagnosis same. Complications none. Discharged Nov. 95 wound healed. Patient feeling very well since operation.

CASE No. 35 Age 35 F Pain in upper right quadrant. Pre-operative diagnosis gall stones. Operation Oct. 5 ether Dr. J. W. Lane cholecystectomy. Post-operative diagnosis same. Complications none. Discharged Nov. 18 wound healed. Patient feeling very well since operation.

CASE No. 3 Ag. 5 F Pelvic pain Pre-operative diagnosis salpingitis. Operation Oct. 5 ether Dr. J. W. Lane salpingectomy. Post-operative diagnosis same. Complications none. Discharged Nov. 5 wound healed. Patient feeling very well since operation.

CASE No. 224 Ag. 4 M Pain in back and hip. Pre-operative diagnosis biliary colic. Operation Oct. 5 ether Dr. J. W. Lane laparotomy. Post-operative diagnosis same. Complications none. Discharged Nov. 5 wound healed. Patient feeling very well since operation.

CASE No. 3 Ag. 5 F Pelvic pain Pre-operative diagnosis salpingitis. Operation Oct. 5 ether Dr. J. W. Lane salpingectomy. Post-operative diagnosis same. Complications none. Discharged Nov. 5 wound healed. Patient feeling very well since operation.

CASE No. 3 Ag. 5 F Pelvic pain Pre-operative diagnosis salpingitis. Operation Oct. 5 ether Dr. J. W. Lane salpingectomy. Post-operative diagnosis same. Complications none. Discharged Nov. 5 wound healed. Patient feeling very well since operation.

CASE No. 224 Ag. 4 M Pain in back and hip. Pre-operative diagnosis biliary colic. Operation Oct. 5 ether Dr. J. W. Lane laparotomy. Post-operative diagnosis same. Complications none. Discharged Nov. 5 wound healed. Patient feeling very well since operation.

SURGERY GYNECOLOGY AND OBSTETRICS

CASE 5 No. 343 Age 50 F Prolapse of uterus. Pre-operative diagnosis, partial prolapse of uterus. Operation Oct 5, ether D J W Lane Murphy suspension. Post-operative diagnosis, same. Complications, none. Discharged Nov 9 wound healed.

CASE 6 No. 365 Age 3 M Constant pain in lower right quadrant. Pre-operative diagnosis, chronic appendicitis. Operation Oct 5, ether Dr J W Lane, appendectomy. Post-operative diagnosis, same. Complications, none. Discharged Nov 8 wound healed.

CASE 7 N 30 Age 5 M Severe pain in gastric ulcer. Operation Oct 5 ether D J W Lane, pylorotomy and gastro-enterostomy. Post-operative diagnosis, carcinoma. Stomach and pancreas. Complications, shock. Died Oct 26 9 6

CASE 8 N 345 Age 40 M Rupture. Pre-operative diagnosis, right inguinal hernia. Operation Oct 5 ether D J W Lane Bassini. Post-operative diagnosis, same. Complications, none. Discharged Nov 14 wound healed, relieved.

CASE 9 No. 380 Age 10 F Pelvic pain. Pre-operative diagnosis, salpingitis. Operation Oct 5 ether D J W Lane salpingectomy. Post-operative diagnosis, same. Complications, none. Discharged Nov 14 wound healed, relieved.

CASE N 513 Age 50 F Prolapse of uterus. Pre-operative diagnosis, prolapse of uterus. Operation Oct 5 ether D L A Supple, Murphy suspension. Post-operative diagnosis, same. Complications, none. Discharged Nov 7 wound healed, relieved.

CASE N 2043 Age 4 F Unmenstruation. Pre-operative diagnosis, retroversion. Operation Oct 5 ether D L A Supple, Gilliam suspension. Post-operative diagnosis, same. Complications, none. Discharged Nov 7 wound healed, relieved.

CASE No. 2059 Age 5 F Acute abdominal pain. Pre-operative diagnosis, right appendicitis. Operation Oct 5 ether D L A Supple, appendectomy. Post-operative diagnosis, same. Discharged Nov 7 wound healed, relieved.

CASE 3 N 204 Age 5 M Constant abdominal pain. Pre-operative diagnosis, chronic appendicitis. Operation Oct 5 ether D L A Supple, appendectomy. Post-operative diagnosis, same. Complications, none. Discharged Nov 7 wound healed, relieved.

CASE 12 N 2057 Age 4 F Persistent vaginal discharge. Pre-operative diagnosis, endometritis. Operation Oct 5 ether D L A Supple, dilatation and curettage. Post-operative diagnosis, same. Complications, none. Discharged Nov 7 wound healed, relieved.

CASE 5 N 2058 Age 31 Pain and swelling in right leg. Pre-operative diagnosis, osteomyelitis of fibula.

Operation Oct 5 ether Dr L. A. Supple, curettage. Post-operative diagnosis, same. Complications, none. Discharged Nov 5 wound draining, relieved.

CASE 6 N 2040 Age 5 F Prolapse of uterus. Pre-operative diagnosis, complete prolapse of uterus. Operation Oct 5 ether D L A Supple, Waitlist suspension. Post-operative diagnosis, same. Complications, none. Discharged Nov 20 wound healed, relieved.

CASE 7 N 206 Age 3 Stiff knee joint. Pre-operative diagnosis, ankylosis of knee joint. Operation Oct 5 ether D Thoma, F Brodbeck resection of knee joint. Post-operative diagnosis, same. Complications, none. Discharged Dec 4 relieved.

CASE 8 N 208 Age 5 F Knock-knee. Pre-operative diagnosis, double genu varum. Operation Oct 5 ether D Thoma, I iliofemoral osteotomy of ilia. Post-operative diagnosis, same. Complications, none. Discharged Dec 4 wound healed, relieved.

Urological Service

CASE 9 N 200 Age 35 M Previous operation for removal of stone from right kidney pelvis Nov 1 9 4. Pre-operative diagnosis, recurrent stone in right kidney pelvis. Operation Oct 5 ether Dr A L Chitt, pyelolithotomy. Discharged Dec 30 relieved. Feb 3 9 6 re-entered hospital on account of urinary fistula in skin.

Operation, Mar 4 9 6 nephrectomy. Operation long and difficult followed by shock. Transfusion good recovery. Discharged Mar 9 6 well. Result, July 9 6 patient without symptoms, urine clear.

CASE 20 N 95 Age 60 M Retention of urine. Pre-operative diagnosis, prostatic obstruction. renal insufficiency. Sept 30 suprapubic cystostomy. renal local anesthesia. Operation Oct 27 ether Dr A L Chitt, suprapubic prostatectomy. Complications, infection following suprapubic salt infusion. Patient failed and died on Nov 5 9 6 N tops.

CASE N 70 Age 5 M Pre-operative diagnosis, acute fibrous contraction of bladder outlet. Operation Oct 20 ether Dr A L Chitt, perineal prostatectomy. Complications, none. Discharged Dec 10 relieved. R ported early in 9 6 that he was without symptoms.

CASE N 53 Age 64 M Retention of urine. Preliminary suprapubic cystostomy under novocaine anesthesia Oct 9 Operation Oct 20 ether D A L Chitt, suprapubic prostatectomy. Complications, none. Discharged in three weeks in good condition.

CASE N 843 Age 37 M Distention of bladder with incontinence. Pre-operative diagnosis, structure of urethra. Operation Oct 8 ether Dr Arthur H (Crosbie) relieved. Result, Mar 6 9 6 N 23 wound healed easily to bladder.

EDITORIAL ANNOUNCEMENT

A consideration of the various methods of shortening the uterine ligaments, as a surgical cure in uterine displacement has been always an interesting subject and one extremely debatable during the past twenty five years. In this time the subject has been reviewed academically at intervals and in every instance a consensus of opinion has been sought regarding the relative merits of the various methods of ligament shortening that have been advocated. Since the review by Alfieri in 1911 no unprejudiced and comprehensive discussion of the subject has been offered. With considerable satisfaction therefore we announce such a discussion of the present status of round ligament shortening in the form of a critical review for the next number of the INTERNATIONAL ABSTRACT OF SURGERY. The author Sidney A. Chaffast of Pittsburgh has brought to bear upon this theme not only the substance of an extensive literature but also a judicious attitude developed out of experience in the ward and operating room.

Other collective reviews to be published during the next few months are:

Mechanism of Fractures	JAMES KIRK, MD, San Francisco
Tuberculosis of the Genito-Urinary Tract	J. H. C. T. GRAY, JR., MD, Boston

INTERNATIONAL ABSTRACT OF SURGERY

OCTOBER 1916

COLLECTIVE REVIEW

THE SURGERY OF GLAUCOMA

BY EMORY HILL, M.D.

Associate Surgeon, New York City

SOME historic perspective is essential to an understanding of the present status of ophthalmic surgery in regard to glaucoma and the voluminous literature of the subject. No ophthalmic topic is more important and perplexing and none lends itself more readily to argument. Wide diversity of opinion must exist so long as several different types of eye disease are included under one name, the etiology of certain types unknown and many surgical procedures effective in selected cases and ineffective in others. Indeed, the phases of the glaucoma problem seem a far from solution today as in the remote past.

The word glaucoma, *glaukos* sea green, dates back to antiquity. It describes the dilated and dilated pupil in eyes with abnormally high tension and in certain other eyes as well. The term was applied to a number of conditions and not until 1856 was cataract differentiated from glaucoma as an opacity of the crystalline lens. Increased intra-ocular tension was recognized by Pater in 1845, but its significance was not understood until Mucklen in 1883 established the involutionary association of urticaroid changes of the eyelids with the clinical picture of the inflammatory type of glaucoma. Before the invention of the Schiøtz tonometer (1903) the inflammatory type of glaucoma was recognized. The study of the eye was made possible by the instrument which revealed the recognition of an inflammatory type of glaucoma in which the effects of hyperemia are not produced and efficient ad-

justment of the intra-ocular pressure is not an inflammatory reaction. In 1881, J. von Leber described the pathologic changes in the deep structures of the eye. Von Graefe in 1881 was the first to call attention to the error but justly directed to the mistake of attributing glaucoma to hyperemia. The relationship of the eye to the circulation is a starting point for a new era in the study of the eye. Von Graefe in 1881 was the first to call attention to the error but justly directed to the mistake of attributing glaucoma to hyperemia. The relationship of the eye to the circulation is a starting point for a new era in the study of the eye. Von Graefe in 1881 was the first to call attention to the error but justly directed to the mistake of attributing glaucoma to hyperemia. The relationship of the eye to the circulation is a starting point for a new era in the study of the eye.

Subsequent studies of glaucoma have been with reference to the anatomy of the eye. The globe further had a partial explanation of the relation of the eye to the circulation. Leber described the pathologic changes of the eye. The anterior chamber and vitreous body were examined these findings anatomically. In 1903, Israel Smith published a paper on the crystalline lens at various periods of the eye during the process of growth of the eye.

especially after the fourth decade producing a disproportion between the lens and the total size of the eye as compared with the proportion in earlier life. In brief the glaucomatous state is brought about by a crowding forward of the iris against the posterior surface of the cornea at its periphery with a consequent blocking of the exit of the aqueous fluid from the anterior chamber into the canal of Schlemm at the sclerocorneal margin. The hypertrophy of the overfunctioning ciliary muscle in the hypermetropic eye favors the blocking of the iris angle, thus hypermetropia is a predisposing factor in glaucoma. Obviously an inflammatory exudate from the uveal tract produces an excess of intra-ocular contents and such exudate may clog the channels of exit.

Thomson Henderson (3) has advanced a theory of glaucoma within the past decade which has aroused much interest. He believes that the pectinate ligament at the angle of the anterior chamber is a cellular structure in early life and becomes progressively sclerosed with advancing age as a result of the influence of the constantly contracting ciliary muscle, to which he believes this ligament serves as a base of attachment. This sclerosis cuts off the exit of the aqueous and places the responsibility of ocular drainage upon the iris veins which may be inadequate to this excessive demand. In the absence of other causes—vascular nervous, or biochemical—no increase of tension will occur, but the sclerosed structure at the iris angle furnishes an anatomical basis for hypertension according to Henderson, when precipitating causes arise. There is frequently a connection between glaucoma and high blood pressure, but the extent to which general arterial hypertension is responsible for ocular hypertension is still in dispute. Intra-ocular hemorrhage may of course, precipitate a glaucomatous attack.

There is no unanimity of opinion as to these various theories, and we must be content at the present time to say that an imbalance between the formation and excretion of intra-ocular fluids, normal or abnormal, gives rise to hypertension of the globe. Variations in intra-ocular tension are quickly compensated for by variations in out flow under normal conditions. Numerous factors may impede drainage and cause hypertension. In the words of Priestley Smith, glaucoma signifies an excess of pressure within the eye, plus the causes and consequences of that excess. It is not a disease entity but a term applied to a symptom-complex which may be the manifestation of a variety of diseased conditions. Indeed, the symptom-complex varies within wide limits,

from the violent inflammatory glaucoma to the simple chronic form of insidious character which some observers would not class as properly the same disease. Moreover glaucoma may be the direct result of a pre-existing or coincident inflammatory process or trauma of the eye (secondary glaucoma) or may be independent of any other demonstrable disorder of the eye (primary glaucoma). A distinct type of the symptom-complex is congenital or infantile glaucoma (hydrophthalmos or buphthalmos) in which the eye is greatly enlarged by stretching of its tunics in intra uterine life or in infancy.

With many kinds of eye disease, varying in cause and clinical course, classed together under one name because of one common symptom, increased hardness of the eyeball and with simple glaucoma remaining one of the mysteries of medical science, it is natural that many kinds of treatment have been tried and none found successful in all cases. The fact that glaucoma is a manifestation not merely of a diseased eye but of a diseased body as well is being emphasized and a more comprehensive study of these cases is being made than in former years. While awaiting the establishment of a definite etiology and an effective prophylaxis it is the difficult task of the ophthalmic surgeon to seek to obtain permanent drainage of the ocular fluids and avoid certain dangers incident to the maintenance of the drainage. The reports of efforts to accomplish this task fill the pages of ophthalmic literature of recent years.

The surgery of glaucoma is discussed at length in the many textbooks of ophthalmology and with especial fullness in the American Encyclopedia of Ophthalmology (4) in which the following convenient classification is made: (1) operations on the posterior half of the globe, (2) operations on the anterior half of the globe, and (3) operations on the sympathetic system of nerves. A brief consideration of the older operations under these three headings will serve as a background to a more critical study of the recent extensive literature dealing with newer operations.

1. *Operations on the posterior half of the globe* consist in puncturing the tunics of the eye (sclera, choroid, and retina) for the purpose of allowing the escape of some of the vitreous humor. This procedure affords a rapid decrease in intra-ocular tension by lessening the intra-ocular contents but is transient in effect as the wound quickly heals. Goulin of Lyons is credited with this operation of posterior sclerotomy as far back as 1769. As now performed the operation

usually requires only local anesthesia (cocaine) after which the conjunctiva is grasped with forceps near the sclerocorneal limbus and the globe rotated so as to allow the entrance of a Graefe cataract knife as far back as possible into the vitreous chamber. A quick puncture of the tunics passing the knife several millimeters in and a slow withdrawal give the minimal result, namely the escape of a small bead of vitreous. A somewhat greater immediate effect and also a more prolonged effect is obtained by an L-shaped incision in which the knife after the puncture is rotated on its long axis 90° and withdrawn so that two linear cuts in the form of a letter L are produced. This wound allows more gaping and heals more slowly than the simpler incision first described.

2 The simplest of the many operations on the anterior half of the globe aims to accomplish the same result. Paracentesis of the cornea is performed by incising this membrane just within the sclerocorneal limbus with a small keratome or a Desmarres needle which is a small lance with a thickening at its base to prevent the needle's entering beyond the desired distance. Slow withdrawal of the instrument with gentle pressure against the posterior lip of the wound allows the anterior chamber to empty. Local anesthesia is often sufficient for this as for the preceding operation, but very high tension with engorgement of the ocular circulation diminishes the effect of local anesthetics and therefore safety sometimes demands the use of general anesthesia. Miotic drugs, as eserine, are practically always used both before and after these operations. The corneal wound can be opened by gentle manipulation with a small spoon or spatula and the effect of the operation renewed for several successive days in this way.

Such transient lowering of tension is of service in the presence of a presumably transient hypertension where permanent relief may be expected in a few hours or days as in the secondary glaucoma occurring in the course of an iridocyclitis or traumatic cataract when the filtration angle is blocked by nival exudate or lens matter or blood. In acute inflammatory glaucoma with a very shallow anterior chamber posterior sclerotomy reduces tension and deepens the anterior chamber sufficiently to allow iridectomy to be performed with safety. It also serves to relieve pain in absolute glaucoma, and to reduce tension temporarily in both acute and chronic secondary glaucoma.

Iridectomy The very brief duration of the beneficial result of these simple puncture operations limits their usefulness. The procedures

promising a more prolonged effect constitute the bulk of the operations performed upon the anterior half of the globe. Of these the classic iridectomy of von Graefe (1850) has been mentioned. The detailed description of the operation is available in the textbooks and need not be repeated here. It is necessary, however, to consider some features of this operation at length in order to understand the present-day problems of glaucoma surgery. Iridectomy is so important an operation that every other method of reducing intra-ocular tension has to bear rigid comparison with this time honored procedure. It is also noteworthy that the excision of a piece of the iris is one step in many other operations whether an essential or a negligible step is a question which concerns us greatly.

The use of miotics and in the presence of an acute glaucomatous attack a preliminary posterior sclerotomy increase the safety of iridectomy. Local anesthesia suffices in non-inflammatory cases but general anesthesia is necessary in the inflammatory type where tension is very high and but little effect is secured from cocaine. A wide keratome is preferred by most operators except when a very shallow anterior chamber makes it difficult to pass a keratome between the cornea and lens without injuring one or the other. In this case a narrow Graefe cataract knife is used. The incision is regulated so as to open the angle of the anterior chamber which is posterior to the visible sclerocorneal limbus. Unless this is accomplished the iris cannot be cut or torn at its ciliary attachment or root and the purpose of the operation is defeated. Therefore the incision and the iridectomy are essentially different from the procedures used when iridectomy is performed for optical purposes and as a preliminary step in the extraction of cataract. Bearing in mind this important difference the surgeon begins his keratome incision 2 mm. back of the upper limbus piercing the sclera with the blade nearly perpendicular then depressing the handle as soon as the tip of the keratome is seen in the anterior chamber and pushing the blade forward between the cornea and iris in the plane of the latter until the incision is 9 or 10 mm. in length. The keratome is then cautiously withdrawn allowing the aqueous to flow out slowly. The incision may be lengthened by pressing the edge of the keratome against one angle of the wound while withdrawing but it is desirable to make the entire incision while the keratome is advancing through the anterior chamber unless the shallowness of the chamber makes sufficient advance of the instrument dangerous to lens and

The withdrawal of the keratome requires great care and precision to avoid a sudden rupture of the aqueous and consequent prolapse of the vitreous with intra-ocular hemorrhage. Beginning with an extremely shallow anterior incision the Graefe knife may be used as in the method for extraction of cataract except that the incision is made 1.5 mm. beyond the visible corneal limbus at one side about 3 mm. the horizontal diameter of the cornea and enters puncture at a corresponding position on the opposite side and the knife emerges 2 mm. behind the upper limbus. Perhaps no more difficult technique is required in the domain of surgery than is demanded of one who operates correctly an iridectomy for glaucoma and the difficulties and dangers of such cases, with the issues at stake are ample; for the large amount of space devoted to this subject in surgical literature. After the operation is completed it is well if local anesthesia is used to place a sterile eye-dropper behind the posterior lip of the wound and making pressure to open the wound slightly place a pledget of cocaine directly on the iris to insure complete anesthesia. Iris forceps are now with closed blades into the anterior chamber opened to grasp the iris near the pupillary margin.

Slowly withdrawing the forceps the iris is drawn through the wound. With the protractor drawn taut a snip is made with iris scissors through the portion of the iris next to the edge of the wound further pulling toward the angle of the wound tears the iris from its attachment and a final cut with the protractor in severing about one fifth of the iris attachment thus opening the angle anterior chamber. Unless the iridectomy is made and extends back to the root of the iris the purpose of the operation is not accomplished. It has not been sufficiently appreciated and it has failed to relieve glaucoma by many are in many instances to be attributed to poor performance of the iridectomy.

It is difficult to formulate any generally accepted theory as to the way in which iridectomy cures of glaucoma or the limitations to the use of this operation. That the pulling of the iris back to its root removes the obstruction to the exit of intra-ocular fluid through the angle of Fontana at the iris angle is perhaps the widely accepted explanation. That the tearing of the iris does not adhere but remain as a space allowing drainage of the aqueous into the veins is an observation which bears upon

this question. It has been maintained that the iridectomy is an unimportant feature of the operation and that the effect is in reality attributable to the scleral incision. It should be emphasized that iridectomy aims to reopen the natural channel of drainage in contrast to some of the more recent operations which attempt to produce new channel. The most positive statement which one can make about iridectomy is that it has a permanent place in the relief of acute inflammatory glaucoma. Whether the new operation will replace iridectomy in this class of cases remains to be seen but for the present no other method of restoring the balance of intra-ocular circulation shows equal results. The earlier the operation the more successful the result. When destruction of the angle is due to vascular congestion and not to permanent adhesion of iris to cornea, as in the chronic type of glaucoma, iridectomy removes the obstruction. In subacute glaucoma the effects are somewhat less sure. In the chronic form (simple glaucoma) the results are not sufficiently uniform to give satisfaction. The tabular iridectomy in acute glaucoma is indicated by the tabulation of Wygodzki (5) showing a favorable outcome in 80 per cent of all cases. In glaucoma simplex statistical report lack conformity. Hallauer (6) found tension reduced to normal in 80.5 per cent of cases with recurrences in 31 per cent. Von Hippel (7) believes that iridectomy is urgently called for as the surest means of combating glaucoma. De Wecke (8) found that nine tenths of a group of 20 ophthalmic surgeons favored iridectomy in glaucoma simplex while the remaining one-tenth considered it comparatively useless. In hemorrhagic glaucoma and buphthalmos iridectomy is disappointing. A persistent effort has been made to find more effective operative procedures for these less favorable types. These methods concern chiefly the drainage of the aqueous and therefore belong in the classification of operations upon the anterior half of the globe. They have been conveniently divided into (a) operations which attempt to effect a communication between the anterior chamber and the subconjunctival spaces (b) operations which attempt to effect a communication between the anterior chamber and the vitreous and (c) operations which attempt to produce drainage through the choroid and the suprachoroidal spaces.

a. The operations which attempt to effect a communication between the anterior chamber and the subconjunctival spaces are based upon the

two procedures already discussed paracentesis of the cornea and iridectomy. Thus de Wecker practiced anterior sclerotomy (1867) in which substantially the incision with the Graefe knife as used in the iridectomy operation is made but a bridge of tissue 2 mm. wide is left intact behind the upper limbus to prevent prolapse of the iris. In this way a filtering cicatrix is utilized for securing additional drainage at the angle of the anterior chamber. De Wecker considered this procedure a valuable preliminary step to iridectomy when the anterior chamber is very shallow. He preferred it to other operations in combination with miotics in chronic glaucoma and in the other types of the disease in which iridectomy is not highly satisfactory as hæmorrhagic glaucoma and buphthalmos and as a means of reducing pain in absolute glaucoma. The operation has not been used extensively in recent years. Various modifications of it were made with the addition of incision into the iris tissue. Panas (9) (1884) practiced iridosclerotomy in which he passed the knife through the iris from before backward traversing the posterior chamber and again piercing the iris before making the counterpuncture. Kries (10) (1893) used a keratome and attempted to produce an indochylolysis pulling the iris away from its ciliary attachment. De Wecker accomplished the same result by tearing the iris with forceps passed into the anterior chamber. De Vincenzus (11) (1893) used a sickle-shaped knife with a convex cutting edge, sweeping around the angle of the anterior chamber cutting the tissues to a depth of 1 mm. or more. Obviously these several methods have the common aim of the original iridectomy operation and all endanger the crystalline lens none of them has become popular.

b The observation that excess of intra-ocular fluids exists mainly in the vitreous chamber as evidenced by the bulging forward of the iris from pressure behind it, has led to attempts to effect a communication between the anterior chamber and the vitreous in order to restore normal depth to the anterior chamber and open the iris angle. Thus Chibret (12) (1898) practiced sclero-cyclo-indic puncture, using a double-edged Graefe knife entering 3 or 4 mm. behind the limbus and passing obliquely through the sclera into the angle of the anterior chamber. The iris was pushed forward by the knife and its ciliary attachment loosened. This procedure was repeated in 5 or 6 meridians. Severe hæmorrhage into the anterior chamber is a disadvantage in such an operation. Sclerotomy in antero-

posterior has been done after an unsuccessful iridectomy. A Graefe knife is introduced into the anterior chamber and passed backward through the coloboma into the vitreous. This is practically limited to use in blind eyes where injury to the crystalline lens is negligible. Fern (13) (1899) practiced cyclo-indo-vitreous puncture after iridectomy. A very small Graefe knife is passed through the coloboma to the circumferential space and lateral movement made to widen the cut. All these methods are so dangerous as to be practically limited to eyes in which vision is already lost. They like the preceding group have not become popular.

c The attempts to produce drainage through the choroid and the supra-horoidal spaces have differed somewhat from the previous group. Here the effort has been to sever the attachment of the ciliary muscle to the sclera. Hancock (14) used a Beer's knife entering at the sclero-corneal limbus below and temporally and incising the sclera obliquely backward for more than one-eighth inch. Walker used a narrow knife entering the cornea just within the limbus with the cutting edge directed away from the anterior chamber. Thrusting through the base of the iris he withdrew by cutting out through the sclera. Quereghni (15) (1900) attempted by means of a scleral incision with a narrow knife to enter the posterior chamber and to incise the choroid by sawing movements from within outward. These operations are dangerous and deserve mention only as predecessors of the more important recent measures.

In addition to these many operations upon the eyeball brief mention must be made of (3) *operations upon the sympathetic system of nerves*. The operation of excision of the superior cervical ganglion was based on the observation that section of the sympathetic results in a soft eye which seems to have been known as long ago as the early years of the eighteenth century. The effect of cutting the ganglion is greater than that of cutting the cord but both are temporary. The influence is probably vascular and muscular through Mueller's muscle at the apex of the orbit. Jonnesco (16) (1899) removed the superior cervical ganglion by means of an incision parallel to the anterior border of the sternomastoid muscle opposite the angle of the jaw dissecting between the carotid artery and vein until the ganglion is exposed behind the artery. The ganglion is freed from its surroundings and cut with scissors the ascending and descending cords are cut likewise. Though favorable results have been re-

ported the effects are not permanent and several deaths have followed. Excision of the ciliary ganglion has also been attempted. Rohmer (17) made a Koenlein resection of the outer wall of the orbit divided the external rectus muscle and passed forceps along the side of the optic nerve attempting to grasp and crush the ganglion. The operation is difficult the actual destruction of the minute ganglion embedded in orbital fat uncertain of accomplishment and the operation has not found favor in spite of some reported successes. Avulsion of the infratrochlear nerve was attempted in 1893 by Badal (18) to relieve pain in glaucoma. The results were temporary. All of these procedures have fallen into comparative disuse and in the literature in recent years no tendency is shown to attack the glaucoma problem from the direction of the sympathetic nervous system.

One new operation upon the posterior half of the globe deserves mention. In 1913 Wichter kiewicz (19) suggested what he termed *sclerodermis cruciata multiplex* where operations upon the anterior half of the globe had failed in securing permanent result. He exposed the sclera extensively by dissecting back a large flap of conjunctiva and Tenon's capsule and made from four to six parallel meridional incisions with a Graefe knife as far back as possible, each 10 to 12 mm long, through the sclera, and then as many more incisions at right angles to the first series. The flap was then sutured into place. Immediate massage enhanced the effect. This operation seems to have made no headway in the presence of the many rivals now attracting attention.

Heine's cyclodialysis (20) is of more importance. The one method of securing drainage through the suprachoroidal space which has obtained favor is that devised by Heine in 1905. He seems to have received the suggestion from Fuchs' observation that detachment of the choroid sometimes follows cataract extraction and iridectomy and occasional subnormal tension. Under local anesthesia a large conjunctival flap is dissected up from the lower temporal quadrant. A 2-mm. cut through the sclera is made 5 mm. back of the limbus and parallel to it. This incision is made carefully with a keratome to avoid injuring the uveal tissue beneath. The black color of the uvea indicates that the sclera has been penetrated. A spatula, slightly curved at the end is passed gently within the scleral wound and worked forward between the sclera and the ciliary body with its plane parallel to these structures until the tip appears in the anterior chamber. Sweep-

ing the spatula from side to side widens the tunnel beneath the sclera. Hemorrhage from the anterior ciliary vessels is a complication which interferes with the good results of the operation unless the blood absorbs quickly injury to the lens must be carefully guarded against. The conjunctival flap is sutured and stitched.

The operation has been advised especially in chronic glaucoma both as the operation of choice and as a resort after iridectomy has failed, in cases in which iridectomy cannot be performed and in puphthalmos. Meiler () has tabulated the results of cyclodialysis as follows: 1) permanent reduction of tension in about 30 per cent of cases after the first three days; 2) temporary reduction of tension in about 40 per cent of cases; 3) the ease of tension recurring after a few days; 4) no effect on tension in about 10 per cent of cases; especially in absolute glaucoma. Wucher and improvement in 57 per cent of cases after 20 being observed for a period of six to seven years; temporary improvement in 25 per cent; 5) showed no improvement. Meiler and Wucher reported 54 operations, concluding that cyclodialysis is designed especially for chronic glaucoma but that it exhibits no marked difference in effectiveness from iridectomy. They emphasize the danger of hemorrhage from the anterior ciliary vessels. Knapp thought after an experience of 18 cases that the operation is not an adequate substitute for iridectomy.

Of chief interest among the innumerable procedures suggested for the relief of glaucoma, in addition to cyclodialysis are those which have come into vogue in the past decade as a result of dissatisfaction with the older methods of treating the chronic types of glaucoma in which iridectomy is of uncertain value. Gradually the opinion that a soundly healed cicatrix possesses filtration properties has lost favor and operators have attempted to produce a permanent path of exit for the aqueous through the scleral tissue by creating a cystoid cicatrix. Two special methods of producing this are by the use of a trephine to remove a button from the sclera, and the deliberate incarceration of iris tissue within the scleral wound. Thus the newer operations may conveniently be studied under the three headings of (1) cystoid cicatrix, (2) trephine operations, and (3) incarceration operations.

1. *Cystoid cicatrix*. The first important operation devised to obtain a cystoid cicatrix was the *iridodesclerectomy* of Lagrange (21) (1906). After the use of cocaine and local anesthesia a

Graefe knife is used as in the operation of iridectomy, puncture and counterpuncture being made well back of the limbus. The knife is turned backward on completing the incision above and emerges very obliquely behind the upper limbus making a large flap. The sclera contained within this flap is then cut out with fine curved scissors. An iridectomy is made and the conjunctival flap replaced. Lagrange at first advised iridectomy in all cases but later limited its use to cases in which there seemed to be danger of prolapse of the iris if left intact. He holds the operation to be especially adapted to simple chronic glaucoma and has protested against its unlimited use in all varieties of glaucoma. The thickness of sclera removed may be regulated according to the amount of weakening desired in the sclera, the amount of sclera excised being in inverse proportion to the degree of hypertension. A valuable discussion of the merits of the Lagrange operation was made by Ballantyne in 1910 (3). Further consideration of it will be given by comparison with some of the other procedures to be described.

Holth's (6) punch forceps operation is an important modification of the Lagrange method. In order to lessen the size of the scleral opening and to regulate the excision Holth made a less extensive incision and having dissected away the conjunctiva from the underlying sclera of the anterior lip of the wound he removed a bit of this scleral flap with punch forceps. The excised sclera measured 3 x 1.5 mm. This operation has been practiced with much success. Butler (24) prefers it to any other on account of ease, safety and quickness of execution.

In 1909, Herbert (25) described what he termed the wedge isolation operation which he considered superior to the Lagrange in that the incision is shorter, the iridectomy smaller and the amount of scleral excision better regulated. This operation has not gained favor to the surprise of those who have witnessed Herbert's results, probably because of the difficulty of gaining a clear idea of the minute details from a written description even so carefully and fully stated as Herbert's own description. The following brief resumé will indicate the difficulty. An old Graefe knife ground down to a breadth of less than 1 mm. is used. Puncture and counterpuncture are made high up so that the anterior chamber is traversed for only a short distance in its upper portion. The incision continued upward and backward until the sclera is cut through but a bridge of conjunctiva is left uncut. The knife is then pushed back into the

scleral wound and turned upward and forward so as to make a second cut through the sclera from behind forward. This serves to isolate a wedge of sclera with the apex toward the anterior chamber. Subsequent shrinkage of this wedge leaves a filtration area. A very small peripheral iridectomy is made without the necessity of cutting the bridge of conjunctiva. Herbert's first report indicated satisfactory results in 10 cases.

Trephine operation. Arkell, Robertson (1) used a scleral trephine fifty years ago. Strahlbridge of Philadelphia, Howes and Butler and Frickhich also used a similar instrument but the procedure seems to have continued only until Fergus (5) used it in connection with a scleral flap. He dissected the conjunctival flap up to the corneal margin and beneath it made a trephine opening through the sclera 2 or 3 mm. back of the limbus. He then passed a spatula through this opening and separated the sclera from the ciliary body and the iris until the spatula appeared in the anterior chamber. Some confusion has arisen between this and the trephine operation of Elliot. The latter is sometimes called the Fergus-Elliot operation. The facts are that Fergus practiced his operation independently of Elliot and before Elliot's first publication (1909) but did not describe it in the literature until a few months later and of more importance the two operations differ in such essential feature that there is no justification for confusing them. Elliot makes the trephine opening in the corneoscleral junction entering the anterior chamber and making an iridectomy. Fergus trephines entirely in the sclera and enters the anterior chamber only after tunneling between the sclera and the uveal tissue. The route for the evacuation of aqueous is different in the two cases.

Elliot's operation (9) was developed from a large experience in the British medical service in India. He dissects up a large conjunctival flap with the base at the upper sclerocorneal limbus. Reflecting this flap over the cornea and holding it with forceps from below, he steadies the globe and continues the dissection with blunt scissors going between the lamellae of the cornea so that the trephine can be placed astride the limbus and the buttonhole include corneal as well as scleral tissue. It is essential that the dissection go below the superficial tissues getting well down to the sclera proper in order not to buttonhole the conjunctiva. The trephine hole is 2 or 2.5 mm. in diameter. Various models with handles constructed for the convenience of the operator and with diameters varying from 1.5 to 3.5 mm. have

been manufactured. Holding the trephine over the limbus, making sure to include the cornea in the incision, the cutting edge is inserted by means of a few twists of the fingers. Further revolving of the instrument effects a passage through the sclera. Experience enables one to be sure that he has entered the sclera without withdrawing to inspect the incision. Firmness in holding the instrument and the use of very little force are necessary. The sensation of resistance to the instrument ceases when the trephine cut is complete and aqueous wells up around the trephine. Elliot makes slightly more pressure on the corneal side of the incision so as to be sure of going well forward and entering the anterior chamber. Thus a hinge may be left on the scleral side of the incision and hold the button which in this use can be removed by one snip of the scissors. This same snip of the scissors may also be utilized for accomplishing a small peripheral iridectomy if the iris presents in the buttonhole. Elliot did not at first regard the iridectomy as an important feature of his operation. In fact he has never attempted to make the type of iridectomy described in the classical operation but practically he finds that a small peripheral iridectomy is useful in preventing prolapse and consequent obstruction of the trephine opening. The conjunctival flap must be carefully replaced. Some operators prefer to secure the flap in place by stitches but it is generally considered sufficient to stroke the flap with a spatula until it is thoroughly spread over its original bed. Eserine is instilled if the iris tends to prolapse otherwise no drops are used. The anterior chamber remains shallow for a long time and the tension correspondingly low. A bleb of conjunctiva indicates the site of the scleral opening.

Fox (30) has utilized the Van Lint sliding flap making a quadrilateral flap of conjunctiva with the attached base at one side so that the flap can be drawn over the upper portion of the cornea, covering the trephine opening, and sutured at the opposite side. David Priestley Smith (31) uses a keratome instead of the trephine and makes a triangular incision in the anterior lip of the keratome wound by means of two converging cuts of the scissors, so that the apex of the triangle points toward the center of the cornea. Elliot in several later contributions has defended his operation for practically all varieties of glaucoma. He now makes an iridectomy in all cases and uses atropine to forestall the "quiet iris" which is likely to occur. He objects to the sliding flap. He does not admit that the technical difficulties

of the operation are beyond the skill of the moderately experienced ophthalmic surgeon.

3. *Incarceration operations* Curiously the accident against which ophthalmic surgeons have always guarded namely the incarceration of iris tissue into the scar of a scleral or corneal wound has been practiced deliberately in recent years. Several observations have led to this. It has been frequently noted that such incarcerations left the tension permanently lowered and that aqueous leaked into the subconjunctival space that in dextromas (or glaucoma) in which the operation was technically most imperfect iris being entangled in the wound gave very satisfactory results and that the danger of infection is minimized if the prolapsed iris is covered by conjunctiva. Therefore several surgeons were bold enough to attempt to incarcerate the iris in a small scleral wound. Herbert (3) has discussed the subject fully in the English literature and has described several procedures in which he has incarcerated iris and also conjunctiva in the scleral incision. Holth (13) has practiced with much success his operation called *iridocentesis*. He makes a very oblique keratome incision beginning far back of the upper limbus so as to have a broad layer of conjunctiva. After a small peripheral iridectomy he draws a fold of iris into the wound and leaves it covered with conjunctiva. The anterior chamber remains empty for a long time. Various modifications of this method have been made. Most of the reports are less favorable than those of Holth himself who records 75 to 85 per cent of cases with satisfactory cataract scars. Schiøtz, on the other hand, obtained only 28 per cent of satisfactory scars.

Borthen's *iridotaxis* (34) is the most important modification of Holth's method. Borthen does not incise the iris but draws it into the wound so that the posterior surface of the iris lies against the conjunctiva with the sphincter well beyond the scleral opening. He uses atropine so that the sphincter will be paralyzed and not tend to draw the iris within the wound. This operation is not advised in the presence of an atrophic iris. Comparison of 26 cases of iridotaxis with 26 done by Holth's method convinced Borthen of the superiority of iridotaxis. Roy (35) has reported favorably on 9 operations after Borthen's method. He emphasizes the importance of a small opening into the anterior chamber just enough to admit the iris forceps so that the iris is held within the wound and does not slip back into the anterior chamber. Roy has not used atropine but is

pleased with the simplicity of the operation and the lack of post-operative irritation. He quotes a personal communication from Borthen stating that the latter has performed iridotaxis 242 times since 1908 and finds no need of using any other method. Borthen considers the good results due to the increased drainage through the spaces of Fontana in consequence of the stretching of the iris rather than to the type of cicatrix. Mayer (36) has sought to accomplish the same end by making an iridodialysis through pulling on the iris with two pairs of forceps and placing the loop of iris thus torn from its base within the scleral wound. He leaves it so for one week when he cuts off the protruding part. Harrower (37) records 7 cases of iridotaxis with good results in every case.

Foreign-body drains Another type of glaucoma operation which promises some usefulness is the insertion of a foreign body drain beneath the conjunctiva and in the anterior chamber. Mayou (38) in 1912 utilized a short thread with a knot tied in it. He pushed the knot into the anterior chamber leaving the two ends of thread in the subconjunctival space with the flap of conjunctiva carefully replaced over it. Zorab (39) in the same month reported his operation of aqueoplasty which differs from Mayou's operation only in the fact that the loop of thread passed into the anterior chamber has no knot in it. The gradual absorption of the thread is thought to leave a fistulous track for the drainage of aqueous into the subconjunctival space. Casey Wood (40) (1915) has modified these procedures in the following manner. He uses a narrow Graefe knife with a hole in the end of the blade like the eye of a needle. After puncture and counter-puncture in the usual way he threads the knife blade with silk and withdraws it through the same openings leaving a double thread in the anterior chamber. The loop of thread is now cut, freeing the knife; thus four ends of thread are left two on each side which are threaded to small curved needles. Each needle is passed as far as possible through the episcleral tissues, each in a different direction. Each thread is now cut at its emergence from the conjunctiva. Four paths of exit for aqueous are thus made by the gradual absorption of the silk. Arthur Prince (41) makes use of a gold horseshoe shaped wire, passing it into the anterior chamber with the ends resting in the scleral wound which is made by either the Lagrange or Elliot method. Vail (42) has recently reported an experience in 1907 with a case of absolute glaucoma in which he in-

serted a silk thread through Tenon's capsule into the vitreous. This resulted in normal tension and absence of pain for a period of two years until the patient's death. Vail suggests the advantage of utilizing a natural channel of drainage such as Tenon's space and avoiding a thin conjunctival covering.

These operations offer the theoretical objection of a foreign substance left within the eye which may excite inflammatory reaction. More time must elapse before any opinion can be expressed in regard to their effectiveness and safety.

This résumé by no means exhausts the list of operations suggested for the relief of glaucoma. It merely covers the more important procedures which are practiced at the present time together with some which are too new to admit of any conclusions. It would be a bold attempt to pass final judgment on the popular operation which have been described; indeed dogmatic statements on the surgery of glaucoma are decidedly out of place. One may hope rather to point out some general principles that seem to be well established and to present the favorable and unfavorable experiences with the several types of operation now in vogue as they are recorded in the literature.

The simple procedures as posterior sclerotomy and paracentesis of the corner still have a place and probably always will as valuable temporary expedients for lowering intra-ocular tension until certain transitory causal factors of hypertension cease to operate and as a preliminary to more radical measures. Massage of the globe deserves a place among these temporary measures. The fulminating type of glaucoma sometimes requires such preliminary treatment before iridectomy can be safely done. The secondary glaucomas can be tided over by such comparatively simple measures until the primary condition is brought under control. The severe pain of absolute glaucoma may be relieved by evacuation of ocular fluids and enucleation sometimes avoided. Acute exacerbations in chronic glaucoma can be likewise handled.

Inflammatory glaucoma has always been the most favorable type for cure by iridectomy. This type is of the nature of an inflammatory edema shutting off the exit of aqueous by the apposition of the iris to the cornea at the angle of the anterior chamber. Removal of a large piece of iris well back at its ciliary attachment is a logical means of removing this obstruction. Results are prompt and permanent in a large majority of cases. It is reasonable to expect

a degree of vision nearly equal to that which existed previous to the attack. The earlier the operation the better the prognosis. An atrophied iris contra indicates the operation, as does a very much contracted field of vision.

If all glaucoma were inflammatory the search for operative means of controlling it would probably have gone no further but the less favorable results of iridectomy in simple glaucoma have created a need for other operations and these operations have been tried also in the inflammatory type. These facts illustrate a tendency, not altogether fortunate, to extend the use of surgical procedures beyond the purpose for which they were first designed and to bring disrepute upon measures which are entirely proper when not misplaced. Thus the Elliot trephine operation and the incarceration methods have been practiced, not only in simple glaucoma in which there has been urgent need for some more effective treatment than iridectomy but also in acute inflammatory glaucoma. Such a series of cases as that of Gross, 237 cases, in which 96 per cent of those iridectomized in the prodromal stage and 87 per cent in the acute stage were successful would convince most surgeons that no more is to be expected from other types of operation than from iridectomy. On the other hand the results of some of the newer operations would justify their use by operators who have mastered their technique. If there were no greater dangers incident to these operations than to iridectomy. Unfortunately however there is the danger of subsequent infection through the thin covering of conjunctiva which is the only protection to the interior of the eye in the operations which secure a cystoid cicatrix. It is too early to say just what place these operations may come to occupy in the treatment of acute glaucoma but for the present it seems wise to depend upon iridectomy in this type of case rather than to risk the danger of late infection after another operation which has not yet proved its superiority. Thus Butler and Evans (43) report a series of 70 cases of acute and subacute glaucoma in which normal tension was secured in 88 per cent after iridectomy and in 83 per cent after various of the newer scleral operations. In the latter cases these authors call attention to the accompanying iridectomy which they believe to be the secret of the good results.

Certain cases of inflammatory glaucoma present technical difficulties to the performance of iridectomy and Heine's cyclodialysis may be utilized instead for example the fulminating type in

which the anterior chamber is obliterated and an iridectomy is impossible and when old people must be operated on who cannot be safely kept in bed. Cyclodialysis is not to be regarded as a satisfactory substitute for iridectomy but may be a necessary expedient to secure a greater effect than the simple punctures of the sclera or cornea.

Glaucoma simplex presents a larger and more difficult problem. This is not the place to enter upon a discussion of the relative merits of medical and surgical treatment for this type of glaucoma. Suffice it to say that there is a considerable trend of opinion in favor of miotic drugs to control tension in these cases. The facts that such drugs are sometimes inadequate and always entail tedious and prolonged administration which few individuals will or can submit to militate against their use without operative intervention. The question therefore is pertinent. What is the operation of choice in simple glaucoma?

The lack of such brilliant results from iridectomy in this type of glaucoma as in the inflammatory type must not be taken to mean that iridectomy is of no avail. Hallauer's figures, showing 80.5 per cent with tension reduced to normal and 35 per cent of recurrences disprove such an idea. Butler and I also record 91 cases of chronic glaucoma with 70 per cent showing normal tension after iridectomy and 87 per cent showing normal tension after trephining. These figures indicate the unsatisfactory degree of effectiveness of iridectomy and the greater value of a cystoid cicatrix. Rochon-Du Signaud (44) states that about 70 per cent of trephine cases in simple glaucoma and chronic glaucoma with inflammatory intermissions are successful. Butler records 23 successful cases in 29 operated upon by Holth's punch method which he preferred to all others in 1909. Morax and Fournere (45) considered Holth's the method of choice and Elliot's next. The value of statistics would be greater if more explicit terms than "successful" were used. It is evident that the past decade has witnessed an important development in the surgery of chronic glaucoma. That a cystoid cicatrix secures drainage of ocular fluids sufficient to keep intra-ocular tension within safe limits, and does this more effectively than iridectomy in this variety of glaucoma is now an established fact. Which of the numerous procedures designed to make such a filtering wound is to be preferred may not be stated with such positiveness.

Elliot believes his operation possesses very

distinct advantages in practically all cases of glaucoma. Lagrange has emphasized the limitations of his operation and insisted that it be not used as a substitute for iridectomy in cases which are most suited to the latter. He reported 84.4 per cent of successes in glaucoma simplex. Meller (46) has made a valuable report on a large series of cases, comparing the Lagrange and Elliot procedures. The Lagrange operation was performed 389 times, the Elliot trephining 15 times. Good results (by which he means sight preserved or if already lost, the globe preserved with normal tension) followed in 69 per cent of the Lagrange operations and in 77 per cent of the trephined cases. The cases terminating badly were grouped together, showing 8.4 per cent in the Lagrange operations and 14 per cent in the Elliot. Meller was impressed with the complications of the Lagrange method and concluded that the smaller scleral opening, far forward in Elliot's method, is a distinct advantage. He found the accompanying iridectomy an important defense against prolapse. He is optimistic about these operations for all cases in which iridectomy is not emphatically indicated; this includes absolute glaucoma, secondary glaucoma and buphthalmos. He credits Lagrange with having paved the way for the safer Elliot procedure. Late infection occurred in 1 per cent of the Lagrange cases and in 17 per cent of the Elliot cases. The fact deserves mention supplementing Meller's report that the Holth punch forceps operation eliminates the chief objections to the Lagrange method with the exception of the necessity of entering a narrow anterior chamber with a knife (which the trephine avoids) and has been used with great success by some operators. Reber (47) feels distinctly more hopeful since the introduction of the Elliot operation. He secured improvement of vision in 13 of 16 cases after this operation; some vision in eyes which were blind when operated upon in 15 cases, and cessation of pain in 6 eyes with absolute glaucoma.

The choice of one of these procedures for securing a cystoid cicatrix is a matter of individual preference on the part of the operator. Whether the incarceration of iris in the wound is an advantage over an iris-free cicatrix is a question which time must answer. Elliot's, Lagrange's, Borthen's and Holth's two operations are just now enjoying much popularity. That possibilities exist of a high degree of development of technique in these procedures is indicated by the fact that the chief objection to the cystoid cicatrix,

late infection of the wound, seems not to be met with by the originators of the operation, while other surgeons are encountering a mishap.

The question of infection through the thin conjunctival covering of the scleral opening is a serious one. While intact conjunctiva is an effective barrier against infection, it is entirely possible that light trauma may at any time cause a minute break in the bulbar conjunctiva which is constantly subjected to by the lid. The most enthusiastic results by the excellent results of these various operations in glaucoma simplex was the abjectly dampened by occasional reports of infection. Up to January 1914 thirteen cases were recorded. Gifford (48) has discussed these at length. Numerous cases have been mentioned in the literature; important observations have been made by Schur, Kuhnt, Axill, and others. Paul has collected a report. May (49) states that nine cases have been reported in these operations, associated with late infection. The mortality which has been experienced by T. Harrison Butler (50) is concluded in an article entitled "The Trephine in Scleritis" with the word "Late infection" a peril which hangs like the sword of Damocles over every eye which possesses a slit-like opening of any type, however obtained. His findings are divided into three classes: 1. Late cases ending in uveitis and panophthalmitis, necessitating the removal of the eye. 2. Case of severe iridocyclitis which destroys the sight. 3. Cases of mild iritis and local inflammation around the aperture which recover. On the other hand, Elliot calls attention to the fact that cases of infection must be judged with regard to the ratio they bear to the total number of cases trephined of which some 100 had been recorded up to October 1914. He makes the following observation: "The condition for which we trephine is not one in which the patient can choose whether he will be operated upon or not. He has his back to the wall and we are fighting for his sight. Risks are then sustainable which would not be worth taking for an operation for cosmetic purposes."

It is impossible to make a generally acceptable statement in regard to late infections. There is no uniformity in experience as yet justifying a final word on the subject. Certainly we cannot be as sanguine in regard to glaucoma simplex as the earlier reports on the new operations seemed to warrant. Yet we cannot fairly offer wholesale condemnation of operations which produce excellent results in a difficult type of disease to

treat, just because a small percentage of the cases suffer from infection at the site of the wound in after months or years. Glaucoma simplex will for the present be combated by means of one of the operations which secure a cystoid cicatrix in the hands of surgeons who are convinced that more cases can be cured by these procedures, after deducting those which later become infected, than can possibly be cured by any other means. This type of glaucoma will not be attacked by means of these procedures in the hands of other surgeons whose fear of late infections leads them to prefer iridectomy or the more temporary expedients coupled with massage and miotics. When cystoid cicatrices are made, patients will be warned that an element of danger exists and precautions taken by frequent irrigation of the conjunctival sac and periodic visits to the ophthalmologist. It seems today that the prognosis of glaucoma simplex is distinctly better as a result of the scleral operations available than it was ten years ago. For a careful exposition of this subject by a master of ophthalmic surgery the reader should consult the textbook of the late Dr. Charles H. Beard (53).

There remain several other types of glaucoma concerning which a few words are necessary.

Hemorrhagic glaucoma does not yield to iridectomy or to the newer scleral operations. There is great danger of destructive hemorrhage following these methods. Anterior sclerotomy is safer as a temporary measure, and may be repeated. Heine's cyclodialysis may be made following posterior sclerotomy. Unfortunately enucleation is the frequent end result of all forms of treatment.

Absolute glaucoma the condition of stony hardness of the globe and extreme pain, may be rendered comfortable at times by posterior sclerotomy and by trephining. These procedures may delay or prevent enucleation.

Secondary glaucoma demands the vigorous treatment of the primary condition. Temporarily the transient punctures of the sclera are utilized. Heine's cyclodialysis promises more prolonged effect.

Buphthalmos is notoriously resistant to all treatment. Anterior sclerotomy may be done repeatedly. Fage (53) reports 14 cases in which this operation gave normal tension and 5 cases in which the growth of the eyeball was checked. Zentmayer (54) has compiled the experiences of a number of surgeons by means of a questionnaire and concludes that some form of sclerotomy is the best procedure of these the Elliot trephining

seems to be preferred. Heine's cyclodialysis has also given some good results.

A discussion of the surgery of glaucoma at the present time must lack finality. The past decade has been fruitful of many ingenious attempts to solve the difficult problem of saving vision in a peculiarly baffling disease. Time will sift these operations selecting the more effective and less dangerous ones for use chiefly in glaucoma simplex. Just now it is more important to study the problem with an open mind than to espouse the cause of any one operator or operation.

ABSTRACTS OF CURRENT LITERATURE

GENERAL SURGERY

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE

Shaw H. A. *Infolding and Peritonealizing Sitch with Application of the Same to Broad Ligament and Gall-Bladder* *Surg. Clin. N. Am.* 9: 6 xxi, 73

Shaw condemns the technique of cholecystostomy as advocated by Williams in *Surgery, Gynecology and Obstetrics*, January 1906. He applies what he calls an infolding and peritonealizing sitch. The advantages claimed for this sitch as summed up by the author are:

Conservation of tissue. In cholecystostomy we are endeavoring to preserve the gall-bladder and rest its function. By this method we certainly do not greatly diminish the capacity of the gall bladder.

2. There is no dead space.
3. It produces perfect inversion in a simple, rapid, and efficient manner.

4. It renders easy the accurate insertion of the drain to just the correct depth. The tack suture in the drain serves the double purpose of fixing it in situ and assisting in preventing eversion of the cut edge.

5. By cutting loop and pulling and tying from both directions, it produces smoother and easier traction and a more symmetrical and tighter purse string around the drain.

The practice of suturing the drain to the abdominal wall is condemned for the following reasons:

It does not allow for the natural mobility of the liver which assumes a somewhat different position, according to posture.

7. The liver to a certain extent participates in the respiratory excursion. Therefore it is unwise to fix the drain to the moving parts, i. e. the abdominal wall and liver.

3. The abdominal sitch is applied after the wound is closed and is almost sure to draw the gall bladder upward or force it into an untoward position.

Shaw then proceeds to apply this sitch to the technique of salpingo-oophorectomy claiming that the special indications of (1) bloodless removal of the mass, (2) closure of the gaping defect in the broad ligament, and (3) peritonealization of denuded areas are all accomplished with rapidity and ease by this

method. He illustrates this procedure by anatomical diagrams.

Arana, G. B. *The Intradermic Suture; Its Technique* *La sutura intradérmica su técnica* *Quinta Med.* 9: 6 xxxi 63

The author discusses the value of intradermic sutures from the cosmetic standpoint in leaving the smallest possible amount of scar on the skin. Chasman introduced this suture method in 1881 and the name of cellular or subcutaneous sutures, and in two recent years, an English surgeon, revised them under the title of subcuticular sutures, although not substantially different from Chasman's, yet coming in the period of antiseptic procedures claimed in the particular attention. Since then the method has been popularized by Lucas and others.

So the description of the technique of intradermic suture is not given as far as Arana can discern from an extensive search in a published work or society report. He describes this technique in the greatest detail and illustrates the various steps of the method so as to make them clearly intelligible. He thinks that this intradermic suture is the only one which is capable of giving a simple linear cicatrix.

With the technique used he considers that longitudinal stitches are best. Horseshoe is used with a Hagdorn needle. It is necessary to obtain a practical acquaintance with the details of the technique as practiced in the operating room. The time consumed is no more than that required for ordinary suturing. Prior to the intradermic suture a continuous suture of the cellular fatty tissues is made which will avoid subsequent hematoma.

Intradermic suture is indicated in all cases where it is desirable to hide a cicatrix and it is formally indicated in interventions on the face, neck, and breast and other visible parts, especially in women. It is employed exclusively in operations which heal by first intention. The method is contra-indicated in septic operations or in cases in which the general state of the patient does not permit of cosmetic considerations. In some cases there may occur as an exceptional result an exuberant cicatrix where the skin is overirritable or very fine, and in such

cases it is necessary to re-operate as the relapse of such an exuberant cicatrix is fatal

W A BRENNAN

Shorten J A.: Continuous Irrigation of Wounds in the Field. *India M Gz* 1916 li 31

The author has devised an ingenious apparatus for continuous irrigation in the field. An empty kerosene tin is placed on a suitable stand and rubber tubing used to siphon the fluid from the can to the wound. By means of adhesive plaster the catheter at the end of the tube is fastened at the desired depth in the wound. The patient's bed is then inclined and the patient turned on his side so as to drain the irrigating fluid and discharges into a rubber sheet draining into a bucket. J H SAILES

Black, C. E.: Some Experiments with Rubber Gloves. *Surg Gynec & Obst* 1916 xxv 0

This paper consists of a series of observations on the sense of touch, in the use of rubber gloves. The author selected six high school students at the Illinois State School for the Blind—3 boys and 3 girls—and had them read a given amount of text (100 words of unfamiliar text) with various weights of gloves and with gloves put on dry, wet and with the hands oiled, gloves which were well fitted and gloves which were loosely and poorly fitted. These various observations were compared with the sense of touch with the bare fingers under the same conditions. The following are the author's conclusions:

1. The use of medium weight rubber gloves requires the blind to use an average of 22 seconds more in reading 100 words of Braille than with the bare fingers, namely 48 seconds with the bare fingers and 60 seconds with medium weight gloves. Or in other words, there is a loss of nearly 30 per cent in the sense of touch judging from the result of this experiment.

2. The tactile sense is materially improved by putting on wet instead of dry gloves, the difference being an average of five seconds, or a little less than 10 per cent. Gloves put on with oil on the hands give a slight improvement over dry gloves, namely 68 seconds as against 60 seconds.

3. The tactile sense diminishes in direct proportion to the thickness of the gloves as shown in our first series of observations where thin gloves showed an average of 1 second, thick gloves showed an average of 106 seconds as against an average of 48 seconds with the bare fingers.

4. A marked improvement in the tactile sense is brought about by the use of carefully fitted gloves as shown in the second series where by "care in fitting" the average was reduced from 60 seconds to 66 seconds.

5. As a final conclusion we may say that the final result of the experiment is that gloves put on wet give the most favorable opportunity for exercising the sense of touch and gloves put on dry give the least favorable.

Bartlett W A: A Clinical and Experimental Study of Post-operative Ventral Hernia. *J Am Coll Surg* 1916 li 31

The causes of post-operative ventral hernia are incisions in abundance of anatomical and physiological principle, improper wound closure, necrosis, infection and tamponade post-operative in healed intra-abdominal pressure and wound union.

Experiment on dogs for union of hernia where one layer was preserved. Hernia resulted where a hole was produced in all layers except skin, muscle and peritoneum, essential repair of these being made by incision of the opposite with overlapping of both healthy fascia lata transposition.

Complete defect were immediately repaired with transplant of fascia, healthy transplant of the reduction of post-operative hernia.

To restore the abdominal wall in these hernias only one to three layers were repaired by union.

The experiment proved that post-operative hernia depends upon two factors, weak wall and hernial tendency.

In the human subject the hernial tendency is corrected pre-operatively by reducing intra-abdominal and intestinal content with rest in bed, liquid diet and catharsis.

The best operative procedure is the airtight utilizing 32 wall and scar tissue but if necessary the abdominal contents may be reduced. If there is undue tension on the reconstructed wall or in the incision with the movements of the lower ribs failure is certain.

Choice of operation depends upon the site of the lesion, the size of the opening and the hernia, the condition of the surrounding tissue and the general condition of the patient.

The varieties of operation are overlapping reconstruction, flap inversion, phlegm and free transplantation.

Kirschner prefers fascia lata because of its easy accessibility in quantity, its strength, inelasticity, adaptability and tendency to heal in.

One reinforcing suture line outside or one inside and outside a complete defect practically insures success.

The after treatment is of vital importance, dealing chiefly with meteorism or straining of any kind.

In the clinical series of 5 operations the results were not known in cases treated with phlegm were failures, 4 had recurrences after the use of the overlapping method while the others were all complete cures.

McVelle O: Pre and Post-operative Care. *Calif St J Med* 1916 li 31

During the past few years many sporadic attempts have been made to standardize the care of the surgical patient both before and after operation. The attempts have nearly always failed to elicit any enthusiasm either because the collaborator had tried to introduce some theoretical methods or

because surgeons as a class, lay more emphasis upon operative technique than upon details of pre and post-operative care. This lack of detail is probably the cause of many poor surgical results.

In this paper the author covers the entire ground of routine pre- and post-operative care in pelvic and abdominal operations upon women. It has been his practice, during the past five years to gradually work up a printed order blank which is left on the patient's chart in the hospital. Enough blank spaces for orders covering individual variations are left on this record but in general, the treatment is very nearly routine.

ASEPTIC AND ANTISEPTIC SURGERY

Maurel: The Method of Action of Certain Antiseptics and of Procedures for the Decolorization of Their Therapeutic Value (Du mode d'action de certains antiseptiques et des procédés destinés à apprécier leur valeur thérapeutique) *Bull Acad. de méd.*, Paris 9 6 1919 48

Maurel calls attention to the results of his experiments, published 5 years ago, on the leucocytes of the blood, which in the light of recent researches on antiseptics have, he believes, a new significance. The results summarized are as follows:

1. That the pathogenic power of microbes appears to depend on two series of products, one series due to their surroundings and the other to their own substance.

2. The product due to their substance has strong effective action on the leucocyte. It is leucocytocidal.

3. According to Maurel's researches certain physical and chemical agents can diminish the action of this leucocytocidal power considerably and help the leucocyte to resist.

4. The diminution of the leucocytocidal power of a microbe can be very marked without its reproductive power being sensibly modified.

5. Iodoform, iodine solutions, and mercuric bichlorid solutions can have a very marked effect on the leucocytocidal power of microbes, or at least on certain ones.

6. It may be concluded, therefore that in order that an antiseptic agent may have a useful effect on the organism invaded by a microbe it is not necessary that the antiseptic kill the microbe or even that it hinder its reproduction. It is sufficient if it diminishes its leucocytocidal power sufficiently that the leucocyte can triumph. W. A. BARNES

Quénecq, E. The Manufacture of Catgut (La fabrication du catgut) *Bull Acad. de méd.* Paris 9 6 1919 530.

The question of catgut is such an important one in surgery that the Paris Academy of Medicine appointed a special commission to consider and report on the condition of its preparation.

Since Pasteur's discoveries objections have been made to catgut as a suture material and although various attempts at sterilization have been made

laboratory experiments have demonstrated that phenic acid, chromic acid, and sublimate have failed to completely sterilize catgut and some surgeons including Kocher and Terrier renounced its use.

Répin's memoir in 1904 showed the futility of existing methods of sterilization and the use of alcohol under pressure was recommended. It was pointed out that sterilization should commence with the preparation of the string in the first stages. Répin's method more or less modified is still in use.

The researches in this field by Gorn and reported to the Academy early this present year based on the attempt to examine of different lots of catgut showed that the sterilization in alcohol at 60 iodine nor objection to heat completely sterilized certain kinds of catgut. Laboratory experiments at the above mentioned fact clinically observed that infection was possible from so-called sterilized ligatures.

The general conclusion of Gorn from his observations is that the surgeon who is responsible to his patient must not rest satisfied with the ordinary phenic acid sterilization but must go back to the manufacture of the string itself in order to be assured that the ligature submitted to sterilization is really sterilizable.

It is an important point of manufacture that Paris and Lyons. The prime beauty in the manufacture of sterilizable catgut is the use of fresh healthy tissues. In Paris alone the entrails of 500,000 sheep are required annually and at Lyons the slaughter of nearly 5,000 is insufficient for the requirement of the catgut trade. Hence it is necessary to resort to Germany and elsewhere to importation of dry and fermented gut and the first question of sanitary inspection of the sheep at the slaughter is lacking. The difficulty of obtaining sterilized surgical catgut is accentuated when it is remembered that sterilization is not so much an object of concern to the manufacturers inasmuch as nineteen-twentieths of their output is destined for the musical instrument trade.

The commission believes that special treatment is essential from the very beginning of the preparation of surgical catgut following immediately on the death of the animal the intestine should be examined, washed and placed in refrigerators removed as quickly as possible to the ligature factory in not less than from twelve to fifteen hours after slaughter and transported in ice. On arrival at the catgut factory the intestines should be immersed in oxygenated water and split into strands or strips and then submitted to the sterilizing processes.

A special apartment in the catgut factory is necessary for surgical catgut and the necessary precautions must be observed in every phase of the manufacture and drying of the strands to prevent contamination of the intimate part of strands either from the personnel or the workmen from the surroundings.

The report of the commission discusses finally the precaution to be observed in the pharmaceutical sterilization and preservation of the sterilized catgut. The commission expresses the opinion that Répin's recommendation that the sterilized catgut suture material be preserved in bouillon and not in antiseptic fluids is the most adaptable to the greater part of the sterilization procedures and that such a tube of catgut carries with it the irrefutable proof of its purity.

W. A. BRENNAN

ANÆSTHETICS

Hering H. E. von Sudden Death in Chloroform Narcosis (Der plötzliche Tod in der Chloroformnarkose) *M. enchen mod. H. k. z. k.* 1916 *Litt.* 521

For the past four years Hering has called attention to his own findings from animal experiment that sudden death in narcosis particularly chloroform narcosis is due to heart flutter. A review of the literature of the past twenty five years shows that this is fairly well established.

Cats and dogs may die suddenly in the beginning of chloroform narcosis and the sudden death in such cases is due to over excitation of the cardiac chambers. In man unquestionably the same thing is true whenever at the beginning of narcosis the heart action is no longer evident and even if respiration has not stopped. In such sudden deaths in man excitation plays its part.

Since extrasystole can be placed in the same category of heart irregularities as heart flutter and may even change into it on the grounds of animal experimentation chloroform should not be administered to patients with extrasystole even when such extrasystole is sporadic only. Moreover since the existence of latent extrasystole can easily be determined chloroform narcosis should be avoided.

W. A. BRENNAN

Bartlett W. A. Method of Facilitating Infiltration Anæsthesia *Am. Surg. Phil.* 96 *Litt.* 678.

In order to avoid loss of time and energy to the operator as well as discomfort to the patient due to the reintroduction of the needle, a number of forms of apparatus have been devised to facilitate the administration of local infiltration anæsthesia. The accompanying cut represents a method which Bartlett has found very efficient and which is very simple. While original with him, a similar apparatus was described by Braun in the second edition of his book. After the usual intradermal injection with a fine hypodermic needle a 9-cm. needle is introduced and a field 18 cm. in diameter can be infiltrated without withdrawing the needle. The graduated container A is filled with 500 to 1000 ccm. of a one half per cent solution of novocaine to which has been added 1 ccm. of adrenalin 1:1000 for every 200 ccm. of novocaine. By means of the two-way cock C the 10-ccm. metal syringe B can be emptied and filled as rapidly as the piston can be forced in and out.

GATEWOOD

Apparatus for administration of infiltration anæsthesia

Leavitt M. A. Rectal Anæsthesia *N. F. M. G.* 1916 *Litt.* 248

The indications for rectal anæsthesia are operations around the head, neck and chest where the element of fear is in evidence.

The method of procedure is as follows: The rectum is prepared by the administration of a cathartic the evening before followed by enemas and suppositories of chlorotone to anæsthesize the rectal mucosa. Twenty minutes after the insertion of the chlorotone morphine and atropine are given hypodermically and twenty minutes later a mixture of oil and ether is introduced in the proportion of 50 to 100 per cent of ether and 50 to 100 per cent of oil. One ounce of the mixture is given for every twenty pounds of body weight not to exceed eight ounces through a rectal tube at the rate of one ounce a minute. In from 10 to 35 minutes the patient goes to sleep. The length of the anæsthesia varies from two and a half to three hours but it may be shortened or lightened by withdrawal of the mixture through a rectal tube. After operation the bowels are massaged and cold water irrigations given to remove the oil and ether. Intravenous injections of normal saline solution may be given if the anæsthesia is too deep.

In only one case was complete failure experienced in the same individual twice. This was thought to be due to resistance to any form of anæsthesia. No untoward results have occurred.

E. K. ARMSTRONG

SURGERY OF THE HEAD AND NECK

HEAD

Morestin II: Very Extensive Shell Wound of the Face. Gradual Reduction of the Resulting Deformity by Successive Extirpation of the Cicatrix (Plaie très étendue de la face par écart d'obus; réduction graduelle de la déformation consécutive par extirpations successives de la cicatrice) *B II et mém. Soc. d'Chir. de Par.* 9 6 xlv, 005

In this article illustrated by photographs which show the very excellent results obtained in a plastic operation for extensive shell wound of the face Morestin calls special attention to the benefits of successive interventions, reducing bit by bit the extent of the cicatrized surface and the mass of sclerous tissue. His knowledge of this gradual method of reduction is based on hundreds of cases of cicatrices and mutilations of the face in his special service. The method is simple as regards manipulations, requires patience and time but gives excellent results, and the author thinks it should play an important part in modern plastic surgery. The method is described in detail.

W. A. BRECKMAN

Eis F. Some Surgical Procedures in Gunshot Fractures of the Mandible. *Practitioner Lond.* 9 6, xcvii, 447

The author tells of his experience while in charge of the surgical side of a military hospital of 350 beds for eighteen months. In many cases the disabilities were present prior to enlistment, but many were accentuated by the unaccustomed physical strain of a soldier's life.

Seventy-one cases of inguinal hernia were operated upon, the Bassini method being used in all except three cases.

Two cases of femoral hernia were also operated upon, Poupart's ligament being stitched to the peritoneal fascia. The after-treatment consisted of twenty-one complete days rest in bed, and the patient was not allowed to resume active duties until three months after the operation.

Sixty-three cases were admitted for operation for varicocele. The high operation over the external ring was done in each case with a vertical incision. These men were kept in bed fourteen days and were given a subsequent furlough of twenty-eight days.

Ten cases of hydrocele were operated upon.

Forty cases of varicose veins were treated surgically.

Thirty-four cases of malformation and malposition of the little toe were operated upon, amputation of the toe being carried out through the metatarsophalangeal joint.

Twent-one cases were operated upon for hammer-toe by removal of the toe.

Four cases were operated upon for hallux valgus and rigidus: excision of the head of the first meta-

tarium was performed in each case. In all but one case there was little or no improvement.

Twenty-one cases suffering from ingrowing toe nail were admitted for operation. The simplest method and one which gave very satisfactory results was to remove the hole of the nail and scrape the nail-bearing area under general anesthesia.

Twenty-three cases of hemorrhoids were subjected to operation, the suture method being preferred.

Twenty-four circumcisions were performed for phimosis, paraphimosis.

Twenty-four internal operations were performed, sometimes with removal of adenoids.

Two cases of internal derangement of the knee-joint were operated upon by resection of the internal semilunar cartilage.

Four cases of undescended testis were operated upon by contrast.

Eight cases of hystula in ano were subjected to operation by contrast.

Five cases with lipoma were operated upon under local anesthesia.

Thirty cases of acute appendicitis were admitted, of which twenty-four were operated upon. There was one death from general peritonitis from perforation of the appendix.

One case of otitis media was admitted which terminated fatally following a tympanocephaloidal abscess.

One case of empyema following pneumonia was operated upon with satisfactory results.

J. H. SKILES.

Baldwin, M. Payne, J. L. Haynes, G. B. and others. Discussion on War Injuries of the Jaw and Face. *Proc. Roy. Soc. Med.* 9 6, v, Odontol. Sect. 05

Baldwin opens the discussion by describing the term, war injuries of the jaws, and the effect of impacts from projectiles on the jaw.

Frequently the bone is not only fractured but comminuted, causing deviation of these fragments, further complicated by the contraction of scar tissue and the formation of diastases if the jaw be improperly treated, or not treated at all. Facial deformities result and the patient's life is made miserable by dribbling of saliva, obstruction of breathing, and many other annoyances. To correct these troubles, apparatus must be used in the mouth, which brings the work inevitably within the sphere of the dental surgeon or stomatologist.

Baldwin visited Paris and Lyons, and found in each of these cities admirable organization of the jaw treatment, and usually a dental surgeon at the head of each establishment. At Lyons, he found under Dr. A. Pont, 350 jaw cases assembled in six large hospitals. Early in the war the lack of stomatologi-

cal service was shown by the number of bad results in these cases. In England, there exists at this time but one military hospital especially set aside for jaw cases. Baldwin believes that it would be well to have such a special hospital in the district of each command in the United Kingdom, and states that the dental and stomatological arrangements of the British army have always suffered from the lack of an experienced officer on the staff of the director general.

Payne relating his personal experience stated that he has treated 22 patients and in addition he visited France in August and December 1915 where he saw large numbers of soldiers suffering from every description of jaw injuries under treatment. The chief trouble he thinks is nearly always with the mandible which is recognized as being the most used bone in the body. It is more liable to serious damage in consequence of its exposed position, its loose attachment to the skull and the action of powerful muscles and the displacements also tend to be relatively greater than in other bones of the body. The mere use of bandages and other external appliances seldom avails to correct this deformity. He suggests the division of these cases into the six following types:

1. Fractures of the mandible without displacement of the line of occlusion.
2. Single fracture of the mandible with lateral displacement.
3. Single fracture of the mandible with vertical displacement.
4. Two or more fractures of the mandible with loss of substance.
5. Gunshot wounds of the maxilla.
6. Fractures involving loss of the anterior portion of the mandible or the maxilla or the whole of one side together with the soft tissue adjacent.

These types are fully described and numerous illustrative cases cited. In answer to the question: At what period after the injury should the aid of the dental surgeon be called in? he answers:

I should emphatically say that it should be done as soon as possible after the wound has been inflicted and I believe that there should be co-operation between the general surgeon and the dental surgeon the dental surgeon beginning his work immediately after the patient has recovered from the condition of shock. Efficient drainage is the first essential principle of treatment. Skilgrams should be taken at the commencement during and at the conclusion of the treatment. Teeth should be freed from tartar blood and food. Carious teeth should be temporarily filled septic roots and teeth should be extracted as soon as possible and any tooth that is situated in the line of fracture usually has to be sacrificed or union may be delayed. The application of a splint should follow as soon as it can be borne by the patient often the temporary appliance may be replaced by a permanent splint when conditions look more favorable. In displacements of the maxilla support may be obtained by

simple bandages or by means of suitable appliances. After sepsis has been controlled the next important step in the treatment is to restore what may remain of the masticatory apparatus by bringing back the fragments of bone into a position which permits of normal occlusion. The treatment may be divided into the four following stages:

1. Reduction of displacement of the fragments.
2. Retention of these fragments in the position which allows of normal occlusion.
3. Reduction of cicatricial contraction the restoration of muscular equilibrium and the remodeling of the facial contour.
4. Fitting of a permanent prosthesis upon the implant the better solution is still uncertain.

The aim of prosthetic treatment should be (1) to correct the deformity and (2) to return the teeth to the position of normal occlusion. To retain the fragment in the position until union has occurred (3) later some form of denture may have to be fitted to make good the gap left by lost bone and teeth and to restore the functional activity of the jaws. The idea that an interdental splint at an early stage will tend to promote sepsis he believes to be entirely erroneous. During the third stage of the treatment frequent massage both manual and electrical by competent nurses should be adopted to restore muscular equilibrium and care should be taken to guard against cicatricial contraction.

HAYES states that no pathological problems or conditions have been met with in this work the difficulties encountered being due to the variety and complexity of conditions presented which demand the most careful consideration. The principal treatment in these cases he believes falls upon the dental surgeon and the ultimate success depends upon the building up and restoring of the jaws as a skeleton or framework upon which the final plastic operation is performed. Much has been done but much remains to be done to supplement the special centers already created for this work in France. There should be dental surgeons at the front to give first aid to these cases and to decide what remaining fragments of jaws and teeth shall be saved and what removed. There are many questions involving the treatment of these wounds now undergoing renewal and general study.

Horz also ventures the opinion that in all jaw cases combined with extensive destruction of surrounding tissue the general surgeon should call the dental surgeon into consultation. He is in favor of simple rubber splints in most cases with the exception of those few in which the steady maintenance of fragments is indicated and he objects altogether to maxillary wiring as this creates a risk of ankylosis being set up. If pressure from the outside is necessary he employs linen bandages or special chin-cups of rubber or metal with hoops fastened together from the attachment of elastic bands that will allow pressure in the direction indicated by the case. He believes that a good method

od of procuring hygiene of wounds in the oral cavity is to suspend receptacle, fitted with a rubber tube and glass cannula, above the head of the patient to fill it with a light tepid solution of from 5 to 10 per cent iodine or chloride of sodium, and to wash out the cavity thoroughly from three to six times a day, according to the septic condition present.

COLYER follows with a brief description of the result of his experience in connection with the Croydon War Hospital. There are one or two main points in connection with the treatment in this hospital of which he speaks. As soon as the patient is admitted to the hospital, a peroxide mouth wash is given every two or three hours, and a 2 per cent solution of iodine is applied once every day. Skilograms are obtained and short notes made. The patient is then taken to the operating theater and given a general anesthetic, usually chloroform. When attempts are made to reduce the various fractures, the septic root is removed as well as the teeth in either side of the fracture. This is a universal rule throughout the hospital. The next step consists of the adaptation of splints, the fixation of which is generally left for two or three days or until there is a certainty that all sources of sepsis have been removed. When the patient is practically convalescent and the fracture is completely healed, a retention splint is inserted also before going back to the front. These soldiers are put through a dietetic course. Before they leave the hospital, they are changed from a liquid diet to a minced one, then to a boiled diet, and lastly to a roast diet.

Colyer believes that the most important displacements in the treatment of jaw cases are those that occur when there is a fracture in the region of the last molar tooth. Very often there is involved loss of tissue to the extent of one-half to three-quarters of an inch. The splints he uses are very simple, one of which he refers especially is known as the skull and mandible splint, consisting of a metallic splint moulded to the outside of the mandible in a knitted kullcap. Ununited fractures are usually due to the presence of a foreign body between the fragments, and secondly to a lack of rest, the foreign body usually being a tooth. Sinuses in connection with fractures of the jaw are, in majority of cases, due to septic teeth. Scar tissue is cut away freely from the jaw and forcible stretching of the soft tissue by means of plugs of vulcanite is adopted.

Stiff jaw, in which the scars have to be stretched is treated by using continuous stretching over a definite period. He has done bone-grafting in two cases, both successfully.

Six FREDERICK EYE believes that the ideal method of bridging over gaps in the mandible is transplantation of bone. This operation is rendered very much easier if splints are firmly cemented to the teeth across the gap. He has transplanted a portion of the eleventh rib. He has not as yet seen a case in which plating in gunshot fractures of the mandible seemed advisable.

HAYES states that the treatment may be divided

into two main stages: (1) the correction of displacement and support of fragments while the healing of soft tissue and bony union is taking place; (2) the fitting of some prosthetic apparatus for the replacing of lost parts, restoration of the function of mastication, possibly also of speech—and reduction of disfigurements. The interval between these two stages should be devoted by the patient to the stitching of the soft tissue and the massage of the voluntary hands that may have formed during the healing of the soft tissue. He believes it important that the splints be simple and aseptic in design and applied in a manner which will avoid the damping of discharges.

MURRAY refers only to the methods dealing with missing portions of the mandible where large or middle portions of the arch have been destroyed, leaving a gap. He is optimistic. Where large portions of bone missing, artificial restoration, he believes is the only course possible in the majority of instances, where a portion extending one-half or three-quarters of an arch are missing, he believes that osteosynthesis will take place in the great majority of cases. He does not believe in the old method of bringing the fractured ends together by wiring them, although he believes that it requires a longer period to obtain a firm bony union across the gap than does when the ends of the fragments are in contact.

NATHAN HAYES views as to plastic operation being performed without consultation with the dentist. He presents the photograph of one patient who had his right maxilla fractured and the mandible in four places with loss of bone on the right and no remaining tooth. The posterior fragment of the occlusion being maintained here by intermaxillary attraction, until a permanent pharyngeal denture can be inserted with reasonable prospect of success. He has also designed a temporary cap splint which is uncemented, has the front cut away, is easily removable, being ligated to three or four teeth, round loops on the lingual side and round vertical wires on the buccal side.

BROWNE says that his experience does not lead him to subscribe to the views of Colyer that the chief thing to seek is bony union even if there should result some lack of normal occlusion. In regard to apparatus, he is in favor of removable rather than fixed splints.

COLYER also dissents from the views held by Colyer on the question of occlusion versus union and believes, as does Hayes, that the presence or absence of a single tooth on a fractured portion may suffice to change the method of treatment entirely, and further he believes that conservation of one or two particular teeth will render relatively easy what would otherwise be a task beset with difficulties. So strongly is he convinced of this, that he has had root treatment carried out on the operating table. He believes, most emphatically, that early reduction and retention of fragments in jaw injuries are effectual

means of combatting sepsis and add materially to the comfort and well-being of the patient. He also thinks that the dental surgeon should be a skilled technician that he should be willing to make his services subserve the immediate and anticipate the ultimate requirements of the surgeon and he believes that the surgeon should have a working knowledge of the range and extent of the dental surgeon's possibilities and that he should know and make known his requirements.

BENNETT believes that in all cases of surgical work on the jaw care should be taken to preserve every tooth that is taken out so that, in peace times they may be examined carefully.

JAMES has found that where there is contraction of scar tissue pressure can be obtained from a length of rubber tubing introduced into the mouth in such a manner as to bring pressure upon the contracted tissue quite thin tubing is used at first and the heavier rubber introduced later. Pressure is obtained by an arrangement of the tube in a U form and it may be increased by tying the two free ends together to form an oval.

PEARCE agrees with Payne and emphasizes the four points with which the latter concludes. He regrets that the authorities have allowed these cases to go six or eight months before referring them to the dental surgeon.

TURNER finds that Dakin's solution is extremely useful in these cases of sepsis. He agrees with the other speakers in the use of cemented splints, especially where there is a possibility of having to remove them in order to extract a root. Regarding the loss of bone he agrees with Mummery. He thinks that all metals used in bone repair are apt to work loose subsequently. Where the cicatrix is once stretched a return may be prevented by the exertion of a small amount of force applied daily.

CARTER believes that wire suturing of the jaw causes fixation at once and is followed quickly by osseous union. He is in favor of silver plated copper wire (No. 10-BWG), and a special key for twisting it up as well as a flexible needle for returning the wire. The drill must not be revolved too rapidly or advance too quickly or necrosis will be caused by heating. A small rubber tube to protect the lips is put over the twisted ends of the wire before being turned down or a thin strip of rubber dam may be wound round them and the two ends tied.

EMIL C. ROBITZEK

Rico 1: Calculus of Wharton's Duct (Calculos del canal de Wharton). *Rep d med y c* Bogotá, 9 6 vil, 343.

Calculus of Wharton's duct is of relatively rare occurrence. The author reports a case in a man of 30. Thirty years previous he had had acute pain in the left submaxillary gland followed by inflammation. Recently the pain reappeared in this region accompanied by fever etc followed by genuine salivary colic and abundant discharge of saliva and pus.

By palpation a hard mass was located in the direction of Wharton's duct and the diagnosis of a calculus was verified by passing a sound. The patient would not permit an incision to be made. Later on the calculus perforated the mucous lining and appeared in the mouth. The abscess rapidly disappeared.

W. A. BELLMAN

Gulbé: Cranial Wounds in War Surgery. *Cand r* al ns u l's plan lu bur d guerre) P s m d 10 p 5

In fifteen months Gulbé has observed 3 cranial injuries of which 23 have been trephined. In the other 14 cases intervention was useless. They all died within 12 hours of their arrival.

As regards the evolution of such injuries Gulbé emphasizes the frequency of cerebral hernia after intervention for penetrating wounds with dura mater injury, also the frequency of encephalitis and the rarity of meningitis.

Non-penetrating wounds in general heal, penetrating wounds on the contrary are almost always fatal. Frontal region injuries are generally more benign than parietal.

Early intervention is necessary. If there is no functional trouble and no evidence of a lesion of the dura mater it is better to abstain from opening it. To prevent cerebral hernia recourse should be had to repeated lumbar punctures, but it is even better to make an early and sufficiently large trephination.

W. A. BRYMAN

Schmidt P: Pneumococcic and Meningococcic Meningitis After Fracture of Base of Skull (Pneumokokken und meningokokke Meningitis na h Schädelbasisfraktur). *Deut he med W k sch* 9 6 Jul 24

Schmidt reports an interesting case of meningitis with double infection by pneumococci and meningococci. The patient, a workman, had suffered a fracture of the base of the skull and was removed to the hospital seven days afterward. He died the next day. Bacteriologic examination of the spinal fluid made on the date of his entrance to the hospital showed pneumococci and meningococci in approximately equal quantities. The blood examination showed only pneumococci.

Autopsy showed a fracture of the upper part of the sphenoid and ethmoid fissure. The dura mater was not injured. Blood-clots and mucus were found in the sphenoidal sinus, the mucosa of the superior nasal cavity was tumefied and inflamed. There was no inflammatory process in connection with the ethmoid and sphenoid. The lungs showed on both inferior lobes bronchopneumonic multiple foci of three or four days' formation.

That the infection of the meninges in this case was direct from the inflamed upper parts of the nasal cavity either through the ethmoid fissure or that of the sphenoid and therefore by the lymphatics and not by the blood seems to the author not to need demonstration. If the infection had been

through the blood it would be natural to expect that this would have shown the presence of meningococci as well as pneumococci. W. A. BRENNAN

Kapocy J. P. Thyroid Tumors of Bones, with Special Reference to Non-malignant, Pulsating Tumors of the Skull. *Surg Gynec & Obst* 19: 6 xxi, 679

The author reviews the literature on thyroid tumors as found in bones and gives a brief résumé of cases thus far reported. He describes in detail a case coming under his own observation. As a result of his study he concludes:

1. That from the literature the majority of investigators conclude that primarily all metastatic thyroid tumors are histologically benign.

2. That metastatic tumors could result from small particles of thyroid tissue which have found their way into the circulatory apparatus.

3. That in many cases of thyroid metastasis there is no hypertrophy of the glands or apparent pathological condition.

4. That the malignant character of some of these tumors is due to some secondary infection possibly engendered by the thyroid cell acting as a focus of continued irritation.

5. That the deposition of embryonic thyroid cells is tenable and may be the greatest factor in the production of thyroid metastases, but the growth of such cells outside of its direct environment is made possible by some peculiar systemic condition as yet unknown.

Leopold S.: Circumscribed Purulent Leptomenigitis Due to Frontal Sinusitis. *J Am Med Ass* 9: 6 April, 1916

Two cases are reported. These cases, as well as a study of the literature, show that the symptoms are frequently preceded by weeks or even months of nasal catarrh with frontal headache or they may occur after only a few days following an attack of influenza. Edema and discoloration of the eyelids, with tenderness over the orbit frequently precede the cerebral symptoms when disease of the wall of the sinus or orbit is present. Frontal headache is present in nearly all cases, though pain in the head is not limited to that region. The pulse and temperature are not characteristic. Rigidity of the neck and Kernig's sign, though noted in both the cases reported are not frequent symptoms. Paralytic symptoms are noted usually in a later stage of the disease. Irritability and restlessness, alternating with clouding of the sensorium, are sometimes the only meningitic symptoms present and death sometimes comes before the development of paralytic symptoms. The pure meningitis following frontal sinus disease is less frequent than brain abscess, but much more frequent than thrombophlebitis.

The explanation of this phenomenon depends on the route of infection which may be direct, through the interstices or necrotic walls, or indirect, through

the venae perforantes of the sinus and orbit or through the lymphatics.

It seems that in many cases the dura escapes involvement that incision is necessary in all cases in which absence of lesions on the surface is noted. This holds true not only for the meningitic cases, but also for the subdural and frontal lobe abscesses. EDWARD L. CORDELL

Hartmann, H. Cranial and Craniocerebral Wounds (Plaies crâniennes et crâno-cérébrales). *Bull. et m. m. Soc. de chir. de Par.* 9: 6, 1915, 1916.

Hartmann's observations are based on 159 cases reported by different operators. Of the injuries 60 per cent were in the parietotemporal region, 18 per cent in the frontal region, 18 per cent in the occipital region. In 13 cases there was a complete fracture of the skull and in 85 of these the dura mater was involved.

The prognosis of cranial injuries by gunshot is grave and varies not only with the intensity but also with the site of the lesion, temporal lesions being the most severe, parietal, frontal and occipital following in severity in the order named. The last gives 100 per cent recovery. W. A. BRENNAN

Villaret M. and F. Uria-Bon. Les Traumatismes de la Tête Apparus dans les Craniocérébrales Wounds of War (Les lésions graves d'apparition tardive des lésions de guerre crâno-cérébrales). *Bull. et m. m. Soc. méd. et chir. de Par.* 9: 6 April, 1916

The authors give particulars of 37 cases of cranial wounds out of a total of 256 which have presented grave accidents appearing several months after the trauma. These cases are classified under four headings: (1) late epilepsy, (2) grave mental troubles, (3) meningeal infection and abscess of the brain, (4) late brain hernia.

Mental troubles and late cerebral hernia are exceptional. The most frequent and important results are late epilepsy and suppurative meningo-encephalitis. Meningitis and suppurative encephalitis were noted in four cases appearing from two to eight months after the trauma. The study of these cases has shown the important part played by the persistence of foreign bodies and metallic debris in the lesion. In the case of late epilepsy it is most interesting from the point of view of the lapse of time after the trauma. In one case this extended to thirteen months but most often it oscillates between four and ten months.

Most of these cases have been trephined for the primitive injury.

The practical conclusions which the authors draw from their study of the cases are that in the case of men trephined or presenting traces of craniocerebral traumas, the future prognosis must be reserved even in the absence of flagrant symptoms of central nervous lesions. Systematic radiologic examination of the cranium should always be made to discover metallic debris or osseous particles.

these are foci which provoke late grave results. Such men should not be returned to the front but kept at duty in the rear under medical supervision.

W. A. BRENNAN

Sharpe, W.: Observations on the Diagnosis and Treatment of Brain Injuries in Adults. *J. Am. Med. Ass.* 1916 lxxvi 1536

The author believes that the mortality of brain injuries in adults has heretofore been high (46 to 68 per cent in all cases) because patients have been allowed to reach the dangerous stage of medullary compression. The signs and symptoms giving warning of increased intracranial pressure and resulting medullary compression are carefully discussed and the importance and value of frequent observation regarding pulse, optic discs, intraspinal pressure and the presence of blood as noted by lumbar puncture repeated if necessary are pointed out.

In a series of recent brain injuries, chiefly fractures of the skull, operation was performed on 79 with only 14 deaths. Operation in the presence of shock with a pulse rate of over 120 is absolutely contra-indicated.

While valuable for diagnosis, lumbar puncture should not be used for the purpose of lowering high intracranial pressure for fear of medullary choking in the foramen magnum.

X-rays are of little importance in the treatment of fractures of the skull.

As regards late results of untreated fractures of the vault or base, the author looked up a series of cases and found 67 per cent were still suffering from the effects of the injury.

The common complaint was headache on exertion. Other symptoms were vertigo, irritability and epileptiform spells, the patients often being disqualified for employment. Of these cases, 4 per cent had had a pulse rate below 70 following injury.

The author believes the late results are due to an increase of intracranial pressure for a long period. Treatment in the majority of cases with increased intracranial pressure should be early decompression. All compressed fractures of the vault should be elevated or removed for fear of later complications. Palliative treatment may assist in bringing about recovery in milder cases but the large proportion require operative relief of the increased intracranial pressure due to hemorrhage or to the increase in amount of cerebrospinal fluid sufficient to produce a wet, oedematous, swollen brain.

In post-traumatic conditions due to long increase of intracranial pressure a large percentage can be improved by operation. The operation of choice in both selected acute and chronic cases of brain injury is subtemporal decompression. The author recommends a straight vertical incision from zygoma to parietal crest and longitudinal splitting of the fibers of the temporal muscle. This gives better hemostasis and union of the divided muscle.

HORACE BIRNEY

Grey E. G.: Studies on the Localization of Cerebellar Tumors — the Pointing Reaction and the Caloric Test. *Am. J. Med. Sci.* 1916 lxxvi 103

The records of 31 cases of cerebellar and extra-cerebellar tumor are discussed relative to the importance of the pointing reaction (Barany) and of the caloric test.

The situation of the growths in the 31 cases was as follows: 3 in the vermis, 10 in the hemisphere, 5 involving the entire cerebellum, 8 cerebellar pontine and 1 extracerebellar.

Concluding that the caloric test has proved to be an important means of differentiating labyrinthine from intracranial disease. Together with the pointing reaction, this test has been found of value in localizing circumscribed lesions in the cerebellum.

In most patients having tumors in the cerebellar-pontine region, new growths and in certain of those with tumors of one or the other hemisphere, the reactions were sufficiently characteristic to be of supplementary value in localizing the disease. In other patients with intra- or extra-cerebellar tumors, the results were often ambiguous at variance with other physical findings and had great reliance been placed upon them, would have led to erroneous conclusions.

There are probably a number of factors responsible for an atypical reaction in patients with cerebellar tumors, among which are: (1) greatly increased intracranial pressure due to internal hydrocephalus, and (2) the diffuse nature of many of the tumors common to the cerebellum. D. L. DESPARD

Livierato Spiro and Cosmettatos G. F.: Tumors of the Hypothalamic Region of the Middle Brain. (*Sui tumori della regione ipotalamica del cervello medio*). *Riforma med.* 96 III 449

Tumors of the hypothalamus of the brain comprise those which develop in the mamillary, hypophyseal and chiasmatic regions. Their development and the consequent compression not only provokes destruction of one of the regions mentioned but also of the nerves which traverse the base of the cranium in the neighborhood of the hypothalamic region and thus produce multiple cerebral phenomena. The symptomatology varies according to the point primarily attacked and the more or less rapid progress of the tumor.

The authors report in detail a case of psammoma of the hypothalamus in a woman of 37. In addition to general and nervous symptoms, the patient showed marked special sensory symptoms. There was complete loss of smell on both sides, also atrophy of the papilla of the optic nerve, both left and right, followed later by amblyopia of the left eye with persistent intense pain. A cerebral tumor was diagnosed and a trepanation done in the right temporal region, but nothing of importance was discovered. The woman died in coma six days after the operation. The tumor was demonstrated at autopsy.

In reviewing the literature concerning the frequency of tumors of the perichiasmatic region the authors find that in the case of tumors developed in the meninges, into which category their own case falls, only three such cases have been reported. They state that the case reported by Hefenrichdorff and their own case constitute a special category, i.e. that of psammomata of the perichiasmatic region, and that these two cases are the first reported up to the present time.

From the anatomoclinical study of their and other cases the authors find that the monolateral involvement of the optic nerve first observed and accompanied by anisometropia fixed the location of the tumor at the anterior angle of the chiasma. This anisometropia which is due to a destructive compression of the perforated anterior subarachnoid space or of the optic nerve has a great diagnostic value particularly when no other nerve besides the optic is involved. The compression or destruction causes degeneration of the nerves of Lancelotti which unite the peripheral and central olfactory apparatus.

The authors claim that craniopharyngeal tumors may develop and attain great size without the hypophysis itself being clearly attacked or disturbed in its functions.

W. A. BAXTER

Carter, M., and Cost, S. Adenocarcinoma of the Cerebellum (Adenocarcinoma del cerebello). *Progr. med. Argent.*, 9 6, No. 30, 30

The author describes the case of a man 3 years old, who had been ill for six months with violent and continuous headaches, localized in the anterior part and right side of the head. He vomited without initial nausea and without the slightest loss of food. At times, nausea was so intense as to interfere with his standing or walking, and he had manifestations of falling on the left side. The patient was constipated. Reflexes, pulse, Romberg, lungs, pupils, etc. were all normal. The urine and blood were negative. Lumbar puncture gave out liquid with normal tension, and flowing drop by drop clear. Apfels and albumin reactions present. Wassermann negative. Lymphocytic sediment.

The patient received bichloride of mercury (0.01 to 0.02 cc) daily intravenously and 4 to 6 gm of KI, daily. His symptoms diminished in intensity for the first week. From the fifteenth day, however, the symptoms increased to such an extent that the patient could not move from his bed. His eyes were closed and he moaned continually. The cephalalgia became so extreme that the patient would take his head between his hands and scream in agony. The headache was no longer frontal exclusively but occipital as well. The position he would assume in preference was right lateral decubitus and pain was evident upon muscular pressure. Babinski sign was present on both sides. Deep and muscular sensations were present. The pupils reacted well, but were found to be unequal. There was left facial paresis in the region of the superior and inferior facial. There was bradycardia

and a depressed intellect. After another lumbar puncture which showed a tubercle bacilli in a positive Wassermann 90 per cent lymphocytes and 10 per cent polymorphs, the patient entered a state of continuous excitement and was unmanageable. Morphine treatment given in repeated doses. The symptoms continued unabated until a comatose condition ensued and death occurred several hours thereafter or about 1 month from the onset of the disease.

As to the diagnosis there were two possibilities: a tumor of the right frontal lobe, with cerebellar symptoms due to counterpressure and a cerebellar tumor in the right hemisphere. An autopsy confirmed the following findings. Dura tense and hyperemic. Cerebrum markedly congested. A macroscopic examination of the cerebellum showed that the entire right lobe and the isthmus were of gelatinous consistency. The border of the posterior margin of the right hemisphere presented a stratification of the circumvolutions, much less than in the left, though an increase of the meninges. A horizontal incision was made passing through the center of both cerebellar hemispheres and comprising the median cerebellar peduncles, also the dentate nucleus. Interesting changes were observed. An enormous mass occupied the posterior third of the right hemisphere and from it flowed a substance of an albuminous consistency, of yellow pinkish color leaving behind a series of cavities, few in number and of various sizes. The mass was of a heterogeneous aspect some parts compact others spongy some hard others soft of a mixed color. The dentate borders in some parts and diffuse in others infiltrating the nervous tissue in some parts, compressing and covering it entirely in others. Vascularly rich. Certain zones were easily emulsified, while the greatest portion of the mass was infiltrated and could not be emulsified. The anterior posterior diameter of the mass was 3 cm. transverse diameter 4 cm. vertical diameter 3 cm. The shape was more or less spherical. Its anterior part was smooth. The cortical substance of the cerebellum was not invaded. It was found compressed and crushed but not attached to the tumor.

A histological study of the tumor showed it to be a tumor of carcinomatous type with cylindrical cells, of the form known as adenocarcinoma. The neoplastic cells showed extreme proliferation. Apparently there was no relation of contiguity or continuity between the carcinoma and the fourth ventricle, whence epithelial plexus could have originated. The cylindrical type of the adenocarcinomatous cells have probably a direct or indirect relation to the ventricular ependyma.

RAOUL L. VIGORAN

NECK

Gelst, G. A. Congenital Cysts and Fistulae of the Neck. *St. Paul M. J.* 9 6, xviii, 57

The author insists that congenital cysts and fistulae of the neck must be divided into two groups,

according to the embryologic origin of each. (1) median and (2) lateral cysts and fistulae. He then takes up the subject of median cysts and fistulae and gives the theories of their origin as outlined by the works of Streckhausen and Hiss.

The views of Wenglowski as published in 1912 are quoted. The site of the opening depends greatly upon the size of the cyst and upon the attachment of the cyst wall to the skin due to inflammatory processes. Cysts are usually irregular in shape projecting into the connective tissue and if ruptured the resultant fistula is tortuous making the passage of a probe difficult. Injection of colored or flavored liquids to determine if possible the communication with the foramen cecum is usually futile unless pathological rupture into the mouth has occurred.

A patient aged 21 years presented a subhyoid median, fistulous opening. Diagnosis was made after an injection of bismuth paste and X ray. Total extirpation of the walls of the cyst was performed with good results.

Lateral fistulae are classified as complete and incomplete and the latter divided into incomplete internal and incomplete external fistulae. The complete occurs in the young or is present at birth but the cyst formation occurs in later life. Fistulae are found more frequently on the right side and are rarely bilateral the external openings are usually single. The secretion is a mucous fluid clear or turbid the amount varying from a few drops to an almost continuous flow.

The caliber of the canal is so small that the finest probe is passed with difficulty or so large as to allow the passage of food particles from the pharynx. Injection of fluid will establish a diagnosis of complete or incomplete fistula. The diagnosis of lateral cysts is not so easy as in the case of fistula.

Geist believes there are two methods in the treatment of cysts and fistulae of the neck. (1) Injection of irritant drugs into the fistula or cyst. (2) total extirpation of the cyst or fistula wall, the latter being the better.

Two cases are reported. One case was a girl of eight years who presented two small openings midway between the chin and the clavicle over the sternocleidomastoid muscle of the right side. The other was that of a woman of thirty years who presented a vertical scar two inches in length in the middle of the border of the sternocleidomastoid muscle, and in the lower end of the scar a small, pin point opening was present. Both were operated upon with good results.

EMIL C. ROBITZKY.

Begoun: Results in Seventeen Cases of Neck Resection in the Secondary Period of Traumatic Arthritis (Résultats de dix-sept cas de résection du coude dans la période secondaire de l'arthrite traumatique). *Bull. et Mém. Soc. de Ch. et Par.* 1916 XLII, 803.

Begoun points out that the enthusiasm of Leriche and other partisans for immediate or very

early resection of the neck in cases of arthritis should be tempered and that the advice of Quenu should be followed who urges that there be further observations before coming to a definite conclusion in the matter.

Begoun gives the results of 17 cases of resection of the neck in cases of arthritis caused by projectiles in which operations have been performed by different surgeons and in which Begoun has had the opportunity of judging the end results which are quite deplorable. Of the 7 cases the neck is unbalanced in 15 and the forearm is not even after effort in the other two the arm is somewhat better but still the patients cannot raise anything to their mouth nor button their clothes.

Begoun thinks that the good results reported have occurred in the case of surgeons who were specially familiar with this resection and were able to devote sufficient time for personal supervision of the after treatment which is most important.

In the hands of the average surgeon he thinks the results will not be better than those reported and he is of the opinion that interference by resection in the secondary period will not give as good results as would be obtained by allowing an ankylosis to be established in good position. Large arthrotomy incisions lavage of oxygenated water curette etc. should be the treatment which will either effect a recovery or leave an ankylosis.

HARTMANN QUENU and BROCA discussed the paper and the general opinions expressed seemed to favor Begoun's views with certain reservation.

W. A. BRENNAN.

Bell & J. Prolonged Use of Tubes Following Diphtheria. *Arch. Pediatr.* 1916 V, 61.

The patient aged one year was suffering from laryngeal diphtheria with a history of having been sick about two weeks. The child was decidedly toxic temperature 103.2 pulse 140 or more and the respirations of the Cheyne Stokes type. There was marked retraction of the chest wall upon inspiration. No membrane was visible upon the tonsils or pharynx. A dose of 20,000 units of antitoxin was injected into a vein and 5,000 into the thigh. The respiratory failure was due to the general toxæmia. On attempting intubation, the patient ceased to breathe and went into profound collapse. The pulse could not be felt nor the heart sounds heard and for several minutes the child appeared to be dead.

A low tracheotomy was done artificial respiration performed and stimulants given. The patient finally began to breathe, at first with only mechanical gasps due to the manipulations and then by the return of the pulse. After breathing began, sufficient air entered the lungs, but a most distressing cough kept up for half an hour or so. This was immediately relieved by allowing two or three drops of a 2 per cent cocaine solution to run down the tube. Steam inhalations and tent were used from the start. For several days rectal feeding was resorted to because of the tendency to choke. On the fifth day a very slight amount of air entered

through the larynx when the opening of the tube was closed. On the seventh day the tube was removed for fifteen minutes. Although some air entered through the normal passage nearly all the breathing was through the opening in the neck.

On the ninth day 50,000 units of antitoxin was given on account of the large edematous swelling of the fauces, which mechanically interfered with feeding. This condition improved the following day. Between the ninth and the twenty-first day there was no change in the tube situation. On the twenty-eighth day the child's temperature was normal for the first time. On the twenty-ninth day the patient's general condition was excellent. The finger was placed over the opening of the tube and a sudden pressure applied to the chest wall with the result that the child uttered a dull cry and

coughed several times. This was successfully repeated every few minutes for half an hour. On the thirty-first day the tracheotomy tube was removed permanently and the child had no further difficulty in breathing through the larynx.

Without warning or physical signs to account for it two days later the child developed a subnormal temperature and typical Cheyne-Stokes breathing. On the thirty-fifth day 50,000 units more of antitoxin (making in all 65,000 units) was given. At this time the throat cultures were still positive. After this further progress was uninterrupted. There were no paralytic signs of any kind. Phonation was normal and the child was discharged in excellent condition after having been in the hospital for two months.

EDW. ED L. CORNELL.

SURGERY OF THE CHEST

CHEST WALL AND BREAST

Durante, L., and MacCarty W. C. Tuberculosis of the Breast. *A. Surg. Phila.* 9: 6 Jan 1908

The authors have observed 10 cases of tuberculosis of the breast. In 3 of them no primary focus was clinically demonstrable. In 3 no clinical tuberculous lesion except the axillary lymphatic involvement was demonstrable, in 1 there was an associated pleurocostal lesion, and in 3 there were evidences of pulmonary tuberculosis.

From a review of the literature the following seem to be the important points in the disease.

The period of greatest susceptibility is between the twentieth and fortieth years. A total of 80 cases have been reported.

Although there is no apparent relationship between the two diseases, 7 cases have been reported in association with neoplastic processes.

3. Practically every case is secondary to a primary focus elsewhere in the body, although infection by way of abrasion in the skin is possible.

Fig. Showing the line of incision. (Jennings.)

4. Most observers have considered the blood stream to be the most common route of infection, though in certain cases the organisms were apparently carried entirely from the neighboring lymphatic glands.

5. A microscopic diagnosis is essential in practically all cases although other means such as cultures, smears, and guinea-pig injections should not be overlooked. GATKHO.

Jennings, J. E. Cancer of the Breast. *N. Y. M. J.* 9: 6, Aug 1900

The author emphasizes the necessity of early diagnosis and operation and points out that 76 per cent of breast tumors in women over thirty years of age are malignant. 11 cases under that age less than 10 per cent are malignant.

The examination of the breast should be thorough. Cancer is more common in the upper quadrant under the nipple and on the outer side. Benign neoplasms occur more frequently in the inner quadrant. Flattening, retraction of the nipple, or shortening of the radial axis is suggestive of carcinoma, especially scirrhus, which causes contraction of the suspensory ligaments of the breast, elevating the affected nipple an inch or more. In late cases when the skin itself is infiltrated, difference in color may be seen or the orange or pig-skin pitting will mark its appearance or chronic eczema with discharge from the nipple.

If the clinical diagnosis is not conclusive, the breast should be explored and the diagnosis made from the gross examination or from frozen sections.

The essentials of a radical removal of the breast is a wide skin incision with a wider removal of the deep fascia, the pectoralis major, minor, axillary fat, and lymphatics. The fascial removal should reach below the areola and the epigastric triangle of Handley. The supraclavicular glands should be

Fig. 2. After the breast has been removed (Jennings)

Fig. 3. Bowel suture line (Jennings)

removed when the growth is in the upper or inner part of breast

Illustrations show the incisions that Jennings has found useful.

D. L. DESVARD

Lenormant, C. Some Observations Regarding the Removal of Projectiles by Thoracotomy (Quelques observations de projectiles lésés par thoracotomie) *Bull et mém Soc de chir de Par* 1916 44, 57

The author reports 8 cases of removal of intra-thoracic projectiles by thoracotomy and the particular point to which he draws attention is the advantage of large pleural openings. He thinks the procedure of choice is the resection of a single rib for a distance of 10 or 12 cm. This can be done bloodlessly in a few minutes and without any ligation being necessary later.

It gives ample opportunity to palpate and examine the thoracic cavity to expose a pulmonary lobe if necessary to approach the mediastinum and to raise and incise the diaphragm.

After operation a few sutures of the soft parts of the intercostal spaces will hermetically close the thoracic breach.

The large opening of the pleura has never been the cause of any accidents in the author's practice. For a long time he insisted on the harmlessness of operatory pneumothorax, and he thinks that recent experience in intrathoracic surgery has confirmed this opinion. The fear of opening the pleura should be dismissed from the surgeon's mind. Under a rigorous asepsis the operations can be done in the thorax just as in the abdomen.

The majority of Lenormant's patients have had a total pneumothorax. None has shown the least respiratory or circulatory incident. If there should be some irregularity of respiratory movements on the entrance of the air traction of the lung will restore order.

In this procedure no drainage is indicated. Resorption of intrapleural air is so rapid that he has not found it necessary to aspirate it.

The cases reported by Lenormant comprise 3 intrapulmonary foreign bodies and 2 foreign bodies

of the mediastinum, one in front of the posterior part of the sides, the other being situated behind the pericardium at the depth of 13 cms.

A sixth case, that of a projectile included in the thickness of the diaphragm. In a patient recently operated upon Lenormant has extracted by transpleural and transdiaphragmatic laparotomy a bullet situated in the convex face of the liver.

W. A. BRENNAN

Burk. Extraction of a Piece of Grenade from the Pleural Cavity by Means of the Electromagnet (Extraction of a Grenade Splinter from the Pleural Cavity by Means of the Electromagnet) *Dtsch Wochenschr* 1916 42, 34

The question as to which should be preferred the operatory method or the use of the electromagnet for the extraction of portions of projectiles retained in wounds or in cavities does not admit of discussion. The operatory method is in the majority of cases the most secure, the easiest and the least dangerous. In the trachea, the esophagus and intrathoracic regions however in which operation is difficult or impossible extraction of the foreign body must be made generally by means of the electromagnet.

The case reported by Burk was that of a soldier who in addition to a gunshot wound had two punctured wounds about the level of the tenth right costal. In the right thorax about the level of the middle of the scapula there was a very pronounced cutaneous emphysema. In the pleural cavity there was evident wheezing which extended to the angle of the scapula. Exploratory puncture was bloody. Resection of the tenth costal released about 500 ccm. of a foetid purulent bloody liquid with little particles of projectile. On recovery from this operation the patient was sent to a base hospital where it was found that the right lung was greatly collapsed and that the pleural wound gave a very foul secretion containing pyococcus micrococci. By means of a sound a fragment of projectile could be felt in the pulmonary pleura about 10 cm. from the operatory wound. The rigidity of the thoracic wall did not favor extraction of the

projectile by the ordinary operative method more over the patient a condition did not warrant further operative damage to the lung. The author therefore determined to endeavor to withdraw the fragment with the electromagnet. After some fruitless attempts he succeeded in extracting the fragment which was about 1.5 by 1 cm. in size. A few days after the extraction the suppuration ceased and within a few weeks there was a gradual extension of the collapsed lung. The patient improved and gained 25 lb. in weight though there was still some mastitis.

W. A. BARNES

TRACHEA AND LUNGS

Green, N. W., and LeWald, L. T. Foreign Bodies in the Respiratory Tract. 4. *Surg. Phila.* 916, 1911, 656.

Although Hippocrates inaugurated intubation of the larynx in order to relieve asphyxiation, very little of note in the treatment of foreign bodies in the bronchi was brought forward prior to the work of Killian in 1896. Since that time many laryngologists and surgeons have interested themselves in this pathological entity with the result that remarkable strides have been made both in diagnosis and treatment.

In the laryngeal portion of the respiratory tract the vocal cords constitute the lumen. In the ventricle of the larynx, objects frequently find lodgment. The next stopping place is at the level of the cricoid. The bifurcation of the trachea rarely arrests an object, as bodies small enough to pass the cords will slip into the bronchus. The right bronchus, from its size and position, is the one most frequently entered. The next point of arrest is in the epibronchial bronchus on the right or the hypobronchial bronchus on the left or in the trunk bronchus on either side. A small body may penetrate the divisions of the trunk bronchus into the various lobe bronchi and their subdivisions.

Foreign bodies may be classified as mineral, metal, or organic. Most mineral and metal objects are revealed by the X-ray. Some organic materials, such as pieces of bone, can be detected in the same way. The most dreaded objects, however, are the organic substances such as seeds and beans, which cast no shadow and which will rapidly

According to Bruening, 69 per cent of foreign bodies occur in children less than twelve years of age. The greatest frequency is at about two years of age.

All recently aspirated foreign bodies should first be sought by the X-ray and the bronchoscope without delay and removed if possible through the mouth. Should this attempt fail a tracheotomy should be done or another effort made by means of the bronchoscope. Failing in this also the wound should be held wide open by wires or by a large tube in the hope that the foreign body may be coughed out. If all attempts at immediate removal

fail, a period usually elapses during which the patient may develop secondary changes in the lung, such as pneumonia, gangrene, abscess and generally an overlying empyema. If he recovers from these acute infections he passes into the class of deferred cases, and removal of the foreign body in these deferred cases does not always effect a cure. The lung abscesses must be treated along surgical lines, and even then it is not always possible to effect a cure but only an amelioration of the affliction.

GATEWOOD

Canuys, G. War Injuries of the Larynx and Trachea (*Les blessures de guerre du larynx et de la trachée*) *J. de méd. & Bordeaux*, 9 8, 1911, 91.

Injuries of the larynx are comparatively rare in war. The statistics of military surgery of former wars show about 6 laryngeal for 10,000 wounds of other organs. In the present war Delorme has stated that wounds of the neck comprise about 3 per cent of all wounds and that wounds of the larynx and trachea are very rare. Gules found in 730 wounds of the head and neck, 17 laryngeal and tracheal. The larynx on account of its great mobility is able to protect itself from a projectile, but in case it is injured the man may die suddenly.

The most important class of injuries referred to by the author are penetrating wounds of the larynx, which have for after-effect a traumatic stenosis either circular or tubular. The treatment of these laryngostenoses consists either in tracheotomy, laryngostomy, tracheolaryngostomy or progressive dilatation. In the latter case after the intervention and insertion of the cannula, the cavity is left open. This cavity is packed above the cannula with iodoform gauze by means of a dressing. The dressing is replaced at the end of fifteen days or three weeks by a canouchou tube the caliber of which is progressively changed. This is open canouchou tube progressive dilatation. When the dilatation is judged to be sufficient, say at the end of five or six months for circular stenoses, twelve to fifteen months for tubular, the canouchou tube is suppressed and a tracheolaryngeal plastic operation is done which constitutes the last phase of the treatment.

W. A. BARNES

Silverstrial, L. Phrenicotomy in the Treatment of Sober Chronic Diseases of the Lung (*La frenicotomia nella terapia di alcune malattie croniche del polmone*) *Riforma med.* 916 xxxiii, 1910.

In recent years several surgical procedures have been suggested or practiced in chronic lung affections, particularly tuberculosis, such as thoracoplasty, artificial pneumothorax, and more recently the phrenicotomy proposed by Sauerbruch.

Silverstrial has made experiments on dogs to test the effects of phrenicotomy either unilateral or bilateral, on respiratory dynamics and on the pulmonary and diaphragmatic tissues. From his experiments he arrived at the following conclusions:

1. Unilateral or bilateral phrenicotomy in dogs is in itself sufficient to suppress lung movement in a practically useful degree.

2. In the early period other respiratory muscle power compensates for the deficiency of diaphragm movement.

3. In the later period this deficiency in the motility of the diaphragm is completely replaced (compensation of contralateral and surrogate innervations).

4. Neither in the early nor late period is it possible to observe any modifications of structure in the healthy lung.

W. A. BRENNAN

Villeon P. de la. Operative Extraction of Intra-pulmonary Projectiles (Extraction opératoire des projectiles intra-pulmonaires). *J. de méd. et de chir. Bordeaux* 1916 lxxvii 7.

In a total of 1,000 wounded which have come under the author's observation there were 80 penetrating wounds of the chest. A large proportion of these were carriers of intrapulmonary projectiles. For their extraction the author sometimes employs a thoracotomy with costal resection followed by pneumotomy and pleuropulmonary suturing consecutive to restoration of the wall, sometimes he extracts under the radioscopic screen following Maudsire's method which he has successfully employed for projectiles having a 10- to 12-cm. parenchymatous depth.

Comparing the procedures he thinks that extraction under the screen is an excellent method, truly marvelous in its simplicity, its rapidity and in the security which it affords. It only occupies a few minutes, sometimes only a few seconds. The patients are up by the fourth or fifth day and pleural and pulmonary rescues are trivial. He reports 20 successful operations 7 of which were performed under the screen.

W. A. BRENNAN

Binet, L.: Indirect Traumatism of the Lung Due to the Nearby Explosion of Large War Projectiles (Les traumatismes indirects du poumon déterminés par l'éclatement à proximité des gros projectiles de guerre). *Presse méd.* 1916 p. 3.

The author cites some illustrative cases to show that after shell explosions although there is no external injury, hæmoptysis of more or less gravity may be found in those who happen to be in the vicinity of the explosion. These sometimes may be very grave as in the case of a soldier dying some moments after a shell burst near him without an external wound and in whom an autopsy showed intrapleural hæmorrhages with rupture of the lungs and gastric hæmorrhage.

Regarding the pathogenesis of such hæmoptysis the author points to two theories: (1) the chemical which suggests pulmonary hæmorrhage due to intoxication and (2) the mechanical, an alteration in the pulmonary parenchyma by modifications of the atmospheric pressure. Both may occur in association. As regards the latter the hæmoptyses ob-

served in such cases are due to an atmospheric depression and are similar to those observed in aeronauts. But in some instances the full winged explosion may be due to impregnation of the udara of a quantity of air into the lung under a strong pressure may cause a rupture of one of the pulmonary vessels giving rise to the hæmoptysis.

HEART AND VASCULAR SYSTEM

Silvan C. A Projectile Penetrating into and Lodging in the Heart (D'un projectile pénétrant et arrêté dans le cœur). *R. M. Chir.* 1916 p. 17.

Silvan reports the case of a soldier with a gunshot wound in which the projectile reached and remained in the heart. The surprising fact was that the functioning of the heart continued to be perfectly normal.

As to the manner in which the projectile reached its position it is not improbable according to Silvan that before becoming fixed in the atria muscle it reached the right ventricular artery where the X-ray examination located it following the direction of the large vessel. It is logical to think that it encapsulated and fixed itself in its position without effect or harm to the circulatory function.

W. A. BRENNAN

Villeon P. de la. Three Juxtacardiac Projectiles Extracted by Three Routes and Different Procedures (Trois projectiles juxta-cardiaques extraits par trois voies et par trois méthodes différentes). *Bull. Mém. Soc. Chir. P.* 1916 p. 90.

The three interesting cases reported by the author are as follows:

The first case was that of a long juxtacardiac projectile resting against the left ventricle and behind it. Extraction by the high thoracic transpulmonary route was followed by recovery.

The second case was that of a juxtacardiac projectile resting against the left ventricle and below it. Extraction by the low abdominal transdiaphragmatic route was followed by recovery.

In the third case there was a juxtacardiac projectile resting against the left lobe, exterior face. Recovery followed extraction under the radioscopic screen.

The three foreign bodies situated in the vicinity of the heart were extracted: one across the lung the second by abdominal route across the diaphragm and the third across the intercostal space under radioscopic control.

Léclerc R. Ablation of a Foreign Body from the Heart Followed by Recovery (Sur un cas d'ablation de corps étranger du cœur suivi de guérison). *R. M. Chir.* 1916 xxxv 4.

Owing to the importance under the present-day conditions of the question of ablation of foreign bodies lodged in the heart, Léclerc publishes the

full details of a case operated by him three years ago in which he extracted a needle fixed in the left lobe of the heart of a child of nine years.

This operation shows that the ablation of a fixed foreign body is less difficult than it is thought to be and that no extensive parietal stripping is necessary. In the case alluded to he resected a costal cartilage and incised the two subjacent cartilages. The heart being exposed he felt nothing on the ventricles on the other hand above the auriculoventricular wall he easily recognized the needle in the lobe.

Holding the needle between his fingers he made a small incision, extracted the needle and sutured the wound. There was perfect recovery.

Leriche thinks that in the case of a bullet a similar procedure could be followed. In the case of a foreign body lodged in a wall, and particularly in a ventricular wall or even a sequestered foreign body in a corner of the cardiac cavity intervention can and should be attempted. The position can be clearly determined by radioscopia.

W. A. BRIDGMAN

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Outland, J. H., and Clendenen, L. Phases of the Chronic Abdomen and of the Acute Abdomen. *Lancet*, 31 J. 9 6 xlvii, 337.

The authors show a few of the numerous pitfalls that beset the diagnostician in certain phases of the chronic and acute abdomen. Several cases are used as illustrations.

Quoting tables from Cabot's differential diagnosis the conclusion is arrived at that two-thirds of the abdominal tumors large enough to be easily palpated through the abdominal parietes are either uterine fibroids, ovarian cysts, enlarged gall-bladders, or gastric neoplasms, and that one-sixth of all such are either tumors of the ovary, intestines, or liver or tubercular peritonitis, or tumor of the spleen or malignant uterus.

The authors recommend these tables in the diagnosing of chronic abdominal conditions, acknowledging, however, their lack of accuracy.

In old people the flabbiness of the abdominal wall must be born in mind as there will be no rigidity in the presence of acute abdominal inflammation.

A résumé is given of a case diagnosed as tuberculosis of the liver owing to pulmonary lesions. Operation was performed and sections of the tumor seemed to resemble tubercular processes. Later on in other hands, the case was proved to be syphilitic.

In the acute abdomen there are no tables of causes and the diagnostician must judge by the symptoms and his experience.

It must be remembered that lobar pneumonia of the right lower lobe can produce pain, rigidity and tenderness in the right side of the abdomen simulating appendicitis.

In ectopic gestation, the symptoms before rupture are always diagnostic and combined with a vaginal examination of sufficient evidence warrant laparotomy.

A case is cited of an acute abdomen resulting from perforation of an old ulcer in the transverse colon following fecal impaction for eight days.

Another very unusual cause of acute abdomen is perforation of the gall-bladder. However, diagnosis of this condition is rarely made before operation.

A case is reported which was diagnosed as acute appendicitis.

The article closes with the warning that in acute abdominal conditions a cathartic should never be given and all food by mouth should be withheld.

P. M. CHASE.

Urbondo C. Serious Esophageal Spasms in Cancer of the Cardia of the Stomach (Espasmos esofágicos graves en el cáncer del estómago alejado del cardia). *Revista Méd. Argent.* 9 6, No. 30, 304.

Esophageal spasms are considered relatively frequent in certain forms of sensory motor gastric neurones, as well as in processes accompanied by these foci.

The author had two such cases which developed insidiously and manifested their violence by the complete transient severe spasm of the esophagus simulating in its evolution a process of complete stenosis of the tube. Some of the symptoms were a progressive dysphagia, mucous expectoration, profuse salivation, secondary inanition, etc.

Cancer of the stomach, in its cycle of evolution, may be local esophageal manifestations which may be confused with an organic process in the tube. In the majority of cases an examination with the sound will reveal the purely functional obstacle which will be confirmed by esophagoscopy.

Notwithstanding that all conclusions are only relative the author considers it important to make a minute physico-functional analysis of the stomach in individuals of certain age in whom there is found a spastic narrowing of the tube without a determinant cause, rebellions to antispasmodic agents and repeated catheterization. At times it is impossible to detect slow processes of gastric degeneration.

RAOUL L. VIGORAN

Quénu E. Extraction from the Abdomen of a Bullet Encysted in the Epiploon, a Year After the Injury (Extraction du ventre d'une balle de plomb enkystée dans l'épiploon, un an après la blessure). *Bull. et Mem. Soc. de Chir. de Par.* 9 6 xlii, 24.

Quénu exhibited a fragment of the great omentum enclosing a bullet. The man was wounded April,

1915 and was operated upon April 1916. In dissection was made under guidance of the Hirtz compass somewhat above the position of Jalaguier's incision. On introducing the finger in the abdomen the extremity of the epiploon was felt pursed and enclosing the projectile. The fragment was excised also the appendix. There was no adherence of the epiploon either with the abdominal wall or the viscera. The bullet had penetrated through the sacral region into the abdominal cavity without involving any viscera. The fluid contents of the epiploic cyst was not quite sterile even after the lapse of a year.

W. A. BRENNAN

Roulier. Note on 46 Wounds of the Abdomen by War Projectiles (Note sur 46 blessures à plaies de l'abdomen par projectiles de guerre). *Bull. et mém. Soc. d' chir. d. P. r.* 1916. Vol. 4.

Of the 46 abdominal wounds reported 31 were perforations. Of these, 4 died almost immediately after arrival at the ambulance and without any intervention. Of the 27 others 15 were operated upon and in 9 no operative treatment was instituted. Of the 15 operated upon 6 recovered and 9 died. Of the 12 treated by abstention 9 recovered spontaneously and 3 after a later intervention.

W. A. BRENNAN

Schwartz, A. and Mocquot, P. The Treatment of Penetrating Abdominal Wounds in the Ambulance (Le traitement des plaies pénétrantes à l'abdomen dans les ambulances). *R. e. de M.* 916. xxv. 36.

The authors submit this as a contribution to the question as to the course to be pursued in the treatment of penetrating abdominal wounds of war, i.e. whether to operate or to abstain.

The arguments advanced against operative treatment are of two varieties—scientific and military.

The scientific arguments are the tendency of such wounds to spontaneous recovery, the baneful influence of the shock and the bad results given by operation.

The authors find that spontaneous recovery of abdominal wounds with intestinal perforation is rare and in cases where recovery takes place it is very difficult to say whether or not there was a real intestinal perforation. In the absence of surgical intervention there is apt to be errors in diagnosing perforating wounds. The fact that certain simple penetrating wounds, or even in rare cases intestinal perforating wounds recover spontaneously is not a sufficient argument against operation. If it can be proved that laparotomy can cure wounds which would not have healed spontaneously.

As regards shock the authors think that the state of shock in which a wounded patient may be is not an absolute operative indication because they think that the best means of remedying the grave conditions which the site of shock indicates is to operate.

Against the third argument the bad results

obtained from operation the authors submit their own statistics. They have done 60 laparotomies for penetrating abdominal wounds. Of these 41 are dead and 19 recovered 31 died within three days after the operation. In these cases lesions were irremediable. Several had fully developed peritonitis they would have died without operation and they died in spite of it.

Of the 19 recovered 15 cases of bad penetrating intestinal wounds 7 had visceral perforations. Some of these might have recovered spontaneously but the greater part have been cured by the operation and the authors think that it requires no argument to show that laparotomy is the best treatment for abdominal wounds.

The argument of a military nature against operation are. The delay in arrival of the wounded, the difficulty of finding aseptic conditions, the length of the operation and the difficulty of handling hundreds of wounded arriving simultaneously.

The first two arguments are easily disposed of by good organization and equipment. The authors have not found it necessary to neglect others in order to perform laparotomy in an ambulance service. Moreover this procedure requires no more time than is required in a serious limb injury.

The indications for operation are discussed also the diagnostic principles, operative technique and operative prognosis. Short details of each of their 60 cases are given.

W. A. BRENNAN

Pfeiffer, D. B. Factors Influencing the Present Mortality of Peritonitis. *J. N. M. J.* 1916. Vol. 604.

With a detailed terminology the present status of peritonitis and its treatment and its influence upon mortality and morbidity is thoroughly and systematically dealt with. Emphasis is laid by the author on those peritonitis which have been analysed with the following findings:

Not purged before admission received 11 deaths.

Operated before admission 22 recovered 15 died 4.

No opiates before admission 4 recovered 14 died 3.

Food or liquid by mouth all

Int. rect. is none

Power or sitting posture none

The author protests against the stereotyped methods of treatment of abdominal pain and colic. The great pitfall for the practitioner lies in the fact that many abdominal pains are not due to surgical conditions and secondly in the difficulty of differentiating surgical disorders in their early stages from the lesser maladies. Until a very few years ago the purge was thought to be a very good introduction to the treatment of any disorder abdominal or otherwise.

When the practitioner learns to treat all cases of abdominal pain with masterly inactivity during the period of indeterminate diagnosis when he

does nothing that runs counter to the principles of treatment set forth when he calls a competent surgeon at the earliest indications for operative treatment, the mortality from the acute abdomen will approach the vanishing point.

EDWARD L. CORRYELL.

Quasella, B. An Interesting Case of Double Retrograde Strangulation (S. di un interessante caso di doppio strozzamento retrogrado). *Glor. d. Accad. di med. d. Torino* 9 3, Ixxviii, 38.

This very interesting and comparatively rare case occurred in a man who while working was suddenly seized with abdominal pains, nausea, and persistent vomiting. The attending physician diagnosed the existence of strangulated inguinal-scrotal hernia which he tried vainly to reduce and had the patient sent to the hospital.

By an incision parallel to Poupart's ligament the hernial sac was isolated and found to contain two intestinal loops in good condition of nutrition and only slightly congested. The existence of a hydrocele was discovered in the right testicle from which a citron-colored fluid escaped. Of the two loops found in the hernial sac, the right was formed from the cecal ampulla with the base of the appendix (about 1 cm.) and the terminal tract of the ileum (25 to 30 cm.) the left from a loop of the small intestine about 30 cm. long.

At operation the abdomen was found to contain a quantity of hemorrhagic, foul-smelling fluid. By traction of the cecum a portion of the ascending colon, normal in aspect and the appendix, which was dark in color evidently by sanguinary infarcts, were extracted. The author then proceeded to extract the segment of the intestine intermediate to the two herniated loops. This for about one-half meter in length was only slightly dilated and blackish blue in color studded with hemorrhagic infarcts and was evidently necrotic. The mesentery for a distance of 6 to 7 cm. from its intestinal insertion showed identical coloration with profuse thrombosis.

The author made a typical psoicectomy followed by resection of the necrotic intestinal segment with circular entero-anastomosis. After the reduction of the intestine into the abdomen the hernial sac was resected and the peritoneal breach closed by linear sutures. The hydrocele sac was partly resected. The patient had fully recovered by the seventeenth day after operation.

In discussing this case the author stated that the term retrograde strangulation was introduced by Maydl in 1895 to indicate the condition by which part of the strangulated organ is found internally in the abdomen while the remainder is found in the hernial sac. Maydl reported two such cases and since then several more have been reported and many theories have been suggested to account for the condition. Nevertheless it must be confessed that retrograde strangulation of the intestine re-

mains today one of the most obscure phenomena in the field of surgical pathology.

The author thinks that the findings in his own case favor the theories of Lauenstein and Lorenz. According to Lauenstein, traction on the two external loops may give origin in the mesentery of the anterior loop to a springing formation in the form of an arc with its concavity toward the ring. Peripherically the mesentery would remain free and fluctuant centrally toward its root it would find itself exposed to a greater or less tension. According to Lauenstein this tension is the impediment to free sanguinary circulation. Lorenz thinks that secondary metemesis of the internal loop makes it rigid so that the peripheral part is constricted and distended causing the production of a sharp angle at the level of the arcade described by Lauenstein.

W. A. BRECKEN.

Chaput. Treatment of Large Crural Hernias by Pediculated Adipose Graft (Traitement des grosses hernies crurales par la greffe adipeuse pediculaire). *Rev. d. chir.* 9 6, xlii, 43.

Chaput finds that most methods in use for the treatment of large crural hernias are inefficient. He now gets excellent results from the use of fat grafts.

The same incision is made as for inguinal hernia. The perit. crum and hernial sac are drawn into the inguinal wound. Supplementary thigh incision being made if required. Sutures are useless for the obliteration of the crural ring. He therefore closes it with pediculated strip of fat which is sutured to the edges of the ring. A rectangular strip is cut about two fingers wide and 10 cm. long, the base of which corresponds to the pubes and the inner border at the media line. The dissection is carried as far as the psoicous. The rectus muscle is incised, the peritoneum tripped from the wall, and the graft introduced. The graft is sutured to Gimbernat's and Cooper's ligaments, and to the crural ring. The summit is divided, the posterior part being fixed to Cooper's ligament behind the crural vein and the anterior part fixed to the crural ring in front of the vein. Chaput has operated upon five patients in this way with a success.

W. A. BRECKEN.

GASTRO-INTESTINAL TRACT

Boss. Occult Bleeding in Ulcus Ventriculi and Stomach Carcinoma (Beitrag zur Kenntnis der okkulten Blutungen bei ulcus ventriculi und Magenkarzinom). *Arch. f. Verdauungskr.* 9 6, xxi, Nos. and 3.

While there is a very great similarity between ulcus ventriculi and carcinoma of the stomach when viewed casually on closer examination it is seen that the occult bleeding which occurs in both differs not only in the manner of occurrence but also in the form. In the case of carcinoma the bleeding

is persistent while in ulcer there is a relatively quick disappearance of the blood also there is a difference in the intensity of the bleeding in both cases. From a consideration of these two differentiating characteristics Boas advances as an essential condition in the diagnosis that examination of the faces alone with regard to the occurrence of occult blood is not sufficient but that the examination of the stomach contents should also receive great consideration. By this procedure it will be possible to reduce the number of unnecessary operations now made in the case of unhealed ulcers which are not recognized as such, and to have such operation reduced to a reasonable limit. W. A. BEECHER.

Leonard V. N., and Dayton A. B. Multiple Acute Gastric Ulcers After Using Percy's Cold Iron for Inoperable Carcinoma. Preliminary Report of a Fatal Case. *J. Am. M. A.* 1916 LV 1 1549.

In this case rigid application of Percy's cold iron was ineffectual in eradicating the carcinoma and was followed by death after four days with lesions similar to those of extensive cutaneous burns.

The case is as follows: A woman, age 52 (two children) had had no bleeding since the menopause at 42 until November 1915. Then she had profuse vaginal bleeding for five days which recurred once. Further symptoms were loss of weight, slight pain, constipation, and painful defecation. Pelvic examination showed the cervix entirely destroyed by a rough firm growth extending far out into each broad ligament fixing the uterus normally in the pelvis.

At operation the technique most recently advocated by Percy was rigidly followed in every detail. On the second, third, and fourth days after the operation there was acute gastric dilatation. On the third day there was a urinary fistula and on the fourth day a paralytic ileus. During preparation for enterostomy the patient died suddenly.

At autopsy the peritoneal cavity contained 100 cc. of serosanguineous fluid with a little fibrinous exudate at the operative site. The intestines were distended. No obstruction could be demonstrated. The pleural cavities each contained 500 cc. of bloody fluid. There were a few subserous ecchymoses. Extensive pulmonary edema was present. The stomach was distended with gas. Its mucosa was perforated by about 24 clean round ulcers which measured from 1 to 10 mm. in diameter. Microscopically the loss of substance extended to the submucosa and was unassociated with any cellular change.

Grossly and microscopically intact squamous cell carcinoma was found peripheral to large areas of general necrosis. Many mitotic figures were seen. In one area seemingly dead carcinoma was found in the midst of normal looking connective tissue. Examination of the regional lymph glands revealed no carcinoma.

F. D. AND L. C. R. LL.

Paucher V. Surgery of the Posterior Wall of the Stomach. Method of Choice in Approaching the Rear Cavity of the Epiploon. (Chirurgie de l'epiploon del'arrière par la voie transperitoneale). *Bull. Acad. Chir.* 1916 LXXV 1 1549.

The author has been using this method since 1911. It is a simple and safe method for approaching the posterior wall of the stomach. It is indicated in all cases of gastric ulcer, gastric cancer, and in all cases of gastric perforation. It is also indicated in all cases of gastric tumor. The author has used this method in all cases of gastric ulcer, gastric cancer, and in all cases of gastric perforation. The author has used this method in all cases of gastric tumor.

The first step is to liberate the transverse colon and separate it from the epiploon. This allows examination of the posterior wall of the stomach. The duodenum and jejunum are then pulled down to the transverse colon. The peritoneum is then raised up the greater curvature and attached to the lesser curvature. The transverse colon is then cut and the duodenum and jejunum are then pulled down to the transverse colon.

The author believes this procedure allows the best exploration of the region of the lesser curvature and facilitates the discovery and removal of lesions which direct exploration does not.

W. A. BEECHER.

Ernst N. P. A Case of Congenital Atresia of the Duodenum Treated Successfully by Operation. *B. M. J.* 1916 LXXXV 1 1549.

The child a boy was robust at birth and there was no history of deformity in his family. He weighed 4,300 gram and showed no external sign of any malformation. From the first the child always vomited after suckling. On the third day he took the breast more actively than at first but two or three hours later he began to vomit with almost explosive violence. A little urine was passed and the movements were limited to a small amount of typical meconium without a particle of digested milk.

At operation an incision between 2 and 3 cm. long was made a little to the left of the middle line. After the anterior sheath of the rectus had been laid bare Mosetig basting was sewed to the edges of the skin with continuous silk suture so that the integuments were completely covered. On opening the peritoneum the dilated stomach protruded into the wound and was traced along the dilated pylorus into the duodenum which was uniformly about two finger breadths in width as far as it could be traced to the upper side of the transverse mesocolon. Below the colon here the intestine reappeared at the flexura duodenojejunalis. It was seen to have collapsed to the caliber of an ordinary pencil about 8 millimeters in diameter. The remaining part of the small intestine was examined quickly especially its lower portion but no stenosis was discovered.

A duodeno-entero-anterior anastomosis was made. A coil of small intestine about four inches below the flexura duodenojejunalis was drawn up in front of the transverse colon and united to the duodenum about the junction of the pars superior and pars descendens.

The intestines were held during the operation by Doyen's straight soft intestinal forceps. Continuous serous suture was applied then a continuous suture through all the layers the entire way around and, finally, a continuous serous suture was applied on the front. When a stomach-tube was passed through it a good deal of air and greenish fluid was discharged. The intestinal forceps were removed and immediately afterwards the jejunum began to fill. The walls of the abdominal incision were united with deep catgut sutures and interrupted silk sutures were applied to the sheath of the rectus abdominis.

A few hours after the operation, the infant was given a weak mixture of milk and water about 30 ccm. every two hours. He vomited a little several times in the course of the day and at 8 p.m. more violently so that the stomach tube was used and a little greenish fluid evacuated. At 7 p.m. an enema was given, but without any result.

The next day he was given one teaspoonful of castor oil twice and three enemas and had altogether four saline discharges, which, without any doubt contained digested milk. The child's appearance was good. No more violent vomiting occurred but there was slight sickness for some days. The bowels acted daily and the stools soon appeared quite normal. The temperature also fell to normal. Five days after the operation the child was sent home to be nursed by his mother. The dressings remained untouched until the fourteenth day when all sutures were removed; the wound had healed by first intention.

The infant's weight decreased during the first five days 90 grams more and was then 3,400 grams or 900 grams less than at his birth but afterward it increased considerably more than 90 grams week continuously for several months. Meals were soon allowed every third hour and when a few weeks had passed, the child could sleep all night without food. He is not remarkably quiet for his age, is vigorous and well developed. His weight one year later was 7,200 grams.

This is the second case of its kind in the literature.

ED. AND L. CORNWELL.

Carman, R. D. The Roentgenologic Diagnosis of Duodenal Ulcer. *Am. J. Roentgenol.* 9:611, 5.

The author's experience in the last year leads him to believe that deformity of the duodenal shadow is a valuable sign in the diagnosis of duodenal ulcer. However errors may arise from the following conditions: (1) Adhesions or spasm may cause an identical deformity. (2) Some ulcers do not produce a deformity. (3) It is sometimes difficult or impossible to sufficiently distend the duodenum to

definitely decide whether deformity is or is not present.

In regard to the first objection, the most common cause of deformity is undoubtedly ulcer.

To the second objection while some ulcers are so very small that they can hardly be palpated at peristalsis, still there is usually an accompanying spasm which causes deformity out of proportion to the lesion and it can be demonstrated by serial radiography. The film in difficult cases the author uses the horizontal position with the patient prone on the right side.

Carman has used serial radiography for a year with what he considers satisfactory results and an increase in correct diagnosis.

Deformities of the bull come under four headings: (1) the greatly distended type resembling a small pine tree; (2) the niche type where the distal part of the ulcer is visible; (3) the incus type single or bilateral; (4) the very small bulb of smooth contour representing a contracted duodenum.

In addition to duodenal deformity the author considers gastric hyperperistalsis, hypermotility with a bulky residue valuable diagnostic signs of duodenal ulcer. Although none of these conditions are pathognomonic of ulcer a proper correlation of the findings taken in connection with the history go a long way toward making the diagnosis. G. W. GAZER.

Martini, T. Chronic Ulcer of the Duodenum and its Gastric Repercussion. (*La ulcera cronica del duodeno sui ripercussioni gastrici*). *Pratt. med. Argent.* 9:6 N. 33, 38.

The indirect symptoms of duodenal ulcer are those showing a reflex alteration in the functions of the stomach.

Among the clinical symptoms that form the classical syndrome of duodenal ulcer the most significant are those derived from secretory and motor disturbances of the stomach.

Martini employs the analytical method, and studies the gastric secretion both before and after the ingestion of the test meal of Edsall and Whither. He then studies the gastric motility by the aid of radiology.

The exploration of the motility of the stomach in the author's cases revealed a marked peristaltic insufficiency with a median gastroparesis and an abnormal elongation toward the right, a hyperfunctional peristalsis, especially expulsive slow and difficult pyloric evacuation, bismuth being found in the stomach six hours after ingestion.

The author found it difficult to make a diagnosis of duodenal ulcer in the presence of the gastronomic correlative syndrome of Reichmann which he considers adaptable to two types of duodenal ulcer: (1) when the ulcer is found situated toward the pyloric sphincter and (2) when besides its location near the sphincter it is complicated at its level by cicatricial retraction and consecutive stenosis. A chronic duodenal ulcer complicated by stenosis

modifies entirely the clinical aspect of a simple ulcer of the same nature. The author considers the surgical treatment as insufficient in 30 per cent of the cases; the only satisfactory relief can be derived from an amputation.

The syndrome of gastric hypersecretion is a part of the type of Haver is the most common finding in the gastric ulcer. Pathology

necrosis, it must be remembered that even a very advanced inflammation of the appendix may be due to an infection of extra-appendicular origin.

To make sure that the appendix is the cause of a peritonitis the epigastrium should be incised and the stomach and duodenum examined. The mere fact that no exudate is noted from this region, is not sufficient because often an exudate finds itself a pathway by the inclined parts to the left and nothing is found in front or to the right.

W. A. BRECKMAN

Guthrie, D. The Prevention of Fecal Fistula in Suppurative Appendicitis. *A. S. J. Phila.* p. 6 July, 1931.

From his experience with 853 drainage cases in which the author has had three fecal fistulae Guthrie concludes that the following factors are of primary importance in their prevention.

The muscle-splitting incision should be used except in those cases in which the abscess is well defined near the median line. In these cases the author believes the straight incision should be used.

The treatment of the stump Whenever possible the author has inverted the stump using two rows of catgut and no non-absorbable material. Where this has not been possible he has resorted to the old cuff operation, turning down a cuff of the thickened peritoneal coat, ligating the stump with catgut and tying the fold of peritoneum over it.

3 The third factor is drainage. The author uses large soft rubber tubes, which he places as far away from the head of the cecum as possible and shortens them as soon as it is deemed safe. Leaks are never given until all drains are removed. He believes that gauze does not act as a drain and is conducive to fistula formation.

GARNWOOD

Secord, E. R., and Correa, L. H. The Results of a Year's Work in the Treatment of Acute Appendicitis. *Cleveland M. J.* 1931, VI, 41.

Of 46 cases of acute appendicitis operated upon by the authors, one died, one of seven cases with generalized peritonitis. Thus it would seem that the mortality rate from acute appendicitis should be very small and it is believed that the important essentials of a non-mortality treatment consist of early diagnosis and removal at the earliest time possible. The authors wish to correct an impression that appendix cases should not be operated upon after the third day unless or until localized abscess has evidently formed. An inflamed appendix should be removed immediately no matter what day of the disease, thus saving a certain large percentage of desperate cases.

A mistaken application of the dictum that elevated temperature is a constant symptom of appendicitis must be avoided. While an elevated temperature is probably always present some time during the course of the attack, it is by no means a constant symptom of a gangrenous or a localized peritonitis. A dead appendix no longer gives the

symptoms of appendicitis and the absence of fever has frequently been responsible for delay on the part of the medical attendant.

If a small portion of the appendiceal stump is opposed, the stump being a potential source of infection and the general peritoneum being better able to deal with it than the tiny sac of peritoneum with which the stump comes in contact after the application of purse string suture. Inversion of the stump without primary ligation is opposed also, because of the danger of hemorrhage. If the appendix contains pus but the peritoneum is free a rubber tissue wick is left down to the cecum in the presence of a localized abscess but drainage is used if generalized peritonitis is present a drain is always placed to the bottom of the pelvis. In all pus cases the immediate use of a stock preparation of mixed infection vaccine is urged. In the latter class of cases the Fowler position and the Murphy drip are also used and if post-operative ileus is feared, injections of eserine are advised.

L. K. ARMSTRONG.

Shaw, H. A. Appendicitis; Some Practical Suggestions Based upon Personal Experience. *Surgical Med.* p. 6 xv, 55.

In general Shaw does not agree with the dictum laid down by Ochsner regarding the time to operate in acute cases nor can he accept Blinn's version—

When a case is seen too late for early operation, and tumor is present and the pulse and general condition and cat dangerous desorption, if the tumor is increasing markedly and there are signs of infection spreading, no surgeon would hesitate as to operation interfere or is imperative because (1) temperature is a most deceptive guide (2) general conditions are often totally at variance with local conditions (3) the impossibility of outlining the tumor mass with rigid belly (4) and, to await the sign of infection spreading seems to be like locking the stable door after the horse is stolen.

Shaw believes that the time to operate upon acute cases of appendicitis is immediately after the diagnosis is made after the twenty-four hour period, opinions and statistics vary which difference, he thinks, is due to poor operative technique and judgment, poor ante- and post-operative treatment and deficient comprehension of the underlying pathological conditions. In over 600 cases, 50 per cent of which were estimated as acute, Shaw has had 6 deaths. He believes that in the surgical treatment of appendicitis there are no hard and fast rules. All preliminary cathartics are contra-indicated on account of the dangers of septic dissemination and the increased post-operative tympany and pain as well as the deferring of the operation for several precious hours awaiting their uncertain action. Where cathartics have been administered, the muscularis is still active for several hours after the operation, terrifically increasing the gas pains and being totally inefficient as a cathartic. He also holds this true of the so-called "high enema."

In the preliminary preparations for the operating

field he believes (1) in a thorough shaving of the whole abdomen (2) a very gentle scrubbing of the abdomen with green soap and a lysol solution rinsing with sterile water (3) application of alcohol packs. The immediate preparation, he believes should be to first mop the umbilical and inguinal regions with benzine sponges followed by fresh benzine sponges for the remainder of the abdomen after drying with a clean sponge a 50 per cent alcohol solution of tincture of iodine is applied followed with a sponge saturated with alcohol to remove the greater part of the iodine. (Since submitting this article for publication the author has adopted the use of McDonald's solution.)

In the making of incisions a thorough anatomical knowledge of the part is necessary especially of the innervation of the abdominal walls since an injury to the nerve supply is far more serious than simple incision of soft parts. In acute cases past the twenty four hour period, the usual incision of choice is the gridiron incision modified to meet the individual indication. Where there is a palpable mass, incision is to the center over the mass. It is well to make the incision moderate at first but susceptible to rapid enlargement the author believes the low "gridiron" incision and when necessary the addition of Harrington's extension to be ideal.

He also believes in the center of the gridiron incision being about one inch lower than McBurney gridiron incision for the following reasons (1) the most difficult part of the operation is the delivery of the appendix without rupture (2) the lesser danger to the twelfth thoracic nerve

The external oblique is cut transversely in emergency this, however being a court of last appeal for it necessitates the severance of the fascia at an angle to the direction of its fiber which, in the presence of infection, means an added danger of post operative hernia. In chronic cases, and those with in the twenty four hour period and those where the tumor mass is central, or when there is doubt whether the lesion is appendicular or pelvic he makes a mediolateral incision, which he considers the most practical incision in surgery because its advantages are multiple and its execution so simple. He has used this incision in more than 1000 pelvic and abdominal cases and has never found cause for regret. The following advantages are claimed: (1) rapidity and simplicity (2) minimum destruction to nerve supply (3) external strong belly wall left due to muscular interposition and lack of organic injury (4) beautiful exposure and ability to make a general exploration and to perform any ordinary work in the lower abdomen or pelvis (5) absence of hemorrhage and no tearing of muscles.

In cases requiring drainage recourse may be had to one of the three following procedures (1) through a simple stab wound away from the primary wound make a hole in the muscle for the drain in line with the skin and facial incision (2) omit tacking muscle to the median line at the lower end of the wound

Shaw never drains through a primary wound but always through a stab wound and where the drain is in proximity to the deep epigastric vessel he ligates the same well above and below the drain. The delivery of a retrocecal appendix he believes can be greatly simplified by mobilizing the lower part of the colon in the conventional manner and tacking it back immediately after the delivery. He does not advise the use of absorbent sutures to bury the stump in the drainage cases but uses instead fine chronic gut mounted on Dulox needles. He believes in removing the appendix when the same can be done without undue risk of breaking up adhesions and dissemination of infection into the general cavity and unduly prolonging the operation in the case of septic or debilitated patients. The appendicular visceral peritoneum in acute cases should be considered as septic and handled gently and if possible should be kept wrapped in gauze from the beginning to the end of the operation. Ligation of the meso-appendix is best accomplished by either the Watkins stitch or by the author's original stitch. Under no circumstances does he irrigate and the use of peroxide of hydrogen he considers little short of criminal. He believes in carbolicizing the stump but does not follow with alcohol and believes in making the purse string suture ample. In cases complicated with dense adhesions, where it appears best to sever the appendix first at the cecal attachment this is done with a knife close against the forceps attached to the distal portion and the stump is hurried at once. He believes it possible to attach towel clips to the peritoneum and in some cases to attach towel clips to the peritoneum the skin and gauze at the same time.

Suggestions as to the type of drainage follows: (1) In simple cases where there is doubt as to the necessity a small cigarette drain is inserted. (2) In purulent cases well walled off where the appendix has been removed a large cigarette drain is employed. (3) In purulent cases where it has been impossible to sever the appendix and there is a well walled off cavity a good sized tubular drain is used. (4) In cases not walled off a large sized tubular drain with one two or three cigarette drains at strategic points is used.

Drainage tubes should be soft should not impinge with force on the debilitated walls of gut and should not come in direct contact with any suture lines involving the gut and should be placed in dependent parts. In cases where the drainage is through a stab wound several strands of silk worm gut are inserted in the lower angle of the original wound where the anesthetic has been unduly prolonged or where the operation has necessarily followed several hours after the ingestion of food gastric lavage is recommended.

In the after-care of drainage cases Shaw uses the Fowler position and the Murphy drip method using sugar instead of salt solution. In the post-operative care of the wound after four or five days when the discharge is extremely thick and heavy it is some-

times washed out with six or eight ounces of salt solution, to mechanically remove the chief amount of debris. After the first forty-eight hours Shaw invariably washes out and fills all cavities and saturates all drains with alcohol (U S P) at least once and sometimes twice, daily for the following reasons: (1) Alcohol is a harmless antiseptic. (2) It is a mild astringent. (3) By its hygroscopic action it promotes a local outpour of serum with its contained anti-bodies. (4) Even when diluted with transudates or exudates it makes a poor culture medium. (5) When it first comes in contact with the great mass of superficial debris, it encapsulates large numbers of micro-organisms. (6) It does not render soluble and wash away the primary plastic lymph, either in the healing abdominal wall or the peritoneal surfaces.

Shaw uses, as a routine, four to eight ounces of saturated solution of magnesium sulphate, at 95° slowly introduced into the rectum with a No. 9 catheter twenty-four hours after the operation, except in cases of extreme debility and anemia.

EMIL C. ROUSSEAU

LIVER, PANCREAS, AND SPLEEN

PERUSSIA, P. Partial Hepatoptosis Due to Interposition (La epatoptosi parziale da interposizione). *Riforma med.*, 9, 6, 1934, 337

Radiologists understand by hepatoptosis the condition shown in the radiologic picture characterized by the transitory and partial interposition of intestinal loops between the convex surfaces of the liver and the diaphragm. It is transitory because it may disappear momentarily owing to changed conditions of meteorism of the intestinal loops, by changes of endo-abdominal pressure, or by changes in the position of the patient. The interposition is partial because the liver does not lose complete contact with the diaphragm, the posterior border maintaining intimate contact with the posterior walls of the abdomen and the diaphragm while the external and anterior parts recede.

In his experience and study of this radiologic picture the author has noticed a certain coincidence of morbid facts which cannot be considered casual and he gives an etiopathogenetic conception of hepatoptosis which is different from that usually accepted. This coincidence consists of organic alteration of the gastro-intestinal tube. Of 5 patients studied 3 showed a pyloric stenosis with grave secondary gastrectasia, in the other 2 there was benign pyloric stenosis with hour glass stomach due to mediogastric stenosis caused by ulceration of the small curvature. In all the 5 cases the interposition of intestinal loops between the liver and diaphragm coincided with a meteoric condition of the colon and the degree of hepatoptosis was proportionate to the intestinal distention.

The authors review the literature of hepatoptosis and show that in the greater part of the observations reported in which the condition of the gastro-

intestinal tract was described the coincidence referred to above was found.

The existence of this coincidence explains the mechanism of the phenomena and leads to a conception of hepatoptosis different from the usually accepted one which ascribes it to anomalies of the methods of fixation. The new conception makes the predominant factor of the phenomenon the alteration of the gastro-enteric tube.

Partial hepatoptosis by interposition is distinct from the wandering liver of Cantani and from Glenard's hepatoptosis, the first showing a complete fall of the viscera and the second showing a false ptosis and a deformed unusually mobile liver.

W. A. BEEHMAN

CASE, J. T. Some Statistics on the Negative and Positive Roentgen Diagnosis of Gall Stones. *Am J Roentgenol.* 9:10 34, 246

The author's statistics may be divided into five groups as follows:

1. Positive roentgen report of gall-stones with stones found at operation: 20 cases out of a total of 4, making percentage of successful positive diagnosis of 49 per cent.

Positive report and no stones found at operation: 4 cases.

3. Negative report and no stones found at operation: 24 cases out of 57 making a percentage of successful negative diagnosis of 95 per cent.

4. Negative report and stones found at operation: 13 cases, failure to diagnose in 5 per cent.

5. Report of probable gall-stones out of 22 cases: 8 were found to have stones, and in 14 no stones were found, a percentage of correct diagnosis of 36 per cent.

Of the 3 cases in Group 4, 9 had disease of the gall bladder other than stone and of the 4 cases of Group 5 where no stones were found 11 had diseased gall-bladders.

Out of a total of 55 cases with diseased gall-bladder X-ray evidence pointed definitely to this condition in 48 cases, or in 88 per cent, while gall-stones were accurately shown in 50 per cent of the cases where they were present.

G. W. GRACE

DEPAGE, A. Note on Twelve Cases of Splenectomy for War and (Not sur cas de splénectomie pour blessures de guerre). *Bull et mém. Soc. de chir. de Paris* 9:6 311, 39.

The earlier reports from the war zone concerning splenectomy for war injuries showed that the operation was almost invariably fatal. The cause was attributed to perturbation in the economy by suppression of a gland all the functions of which are not yet known.

DePage has up to now practiced 12 splenectomies with 8 deaths. Of the 12 there were 4 in which the spleen alone was injured and of these there were 3 recoveries. In the other 8 cases the injury to the spleen was accompanied by injuries of other organs.

tures mostly due to shells. The treatment consists in clearing of the wound drainage use of Dakin's solution, immobilization daily dressings. Drainage was as free as possible and whenever there was any increase in temperature or pain, fresh drainage incisions were made.

Of the 4 cases 3 died had amputations in 6 there was complete consolidation recovered with pseudo-arthritis 3 are in process of recovery. One of the deaths was due to septicemia, and the other to a severe bladder injury the fracture progressing favorably. W. A. BRYAN.

Sever, J. W. Fracture of Tuberosities of the Tibia. *Am J Orth Surg* 9 6, xiv N 5

The author reports three cases that are under his observation which were all traumatic in origin. In such cases there is produced a condition of knock-knee and joint-strain which causes a change in the weight-bearing surface of the knee joint. He thinks balancing of the foot and leg in proper weight-bearing lines will relieve the knock-knee and joint strain. He quotes Jones' report of two cases. Fowler a one case and Lange two cases.

PETER LEWIS

Robinson, E. F. Fracture Dislocation of the Astragalus. *J Surg Pathol* 9 6, xviii, 606

The author's experience has been unsatisfactory with the older methods of treatment of fracture dislocations of the astragalus and he has found that the recipient was more or less of a cripple the remainder of his life.

In the case reported he shows an excellent result attained by open operation after the usual manipulation under anesthetic proved of no avail. An incision four inches over the outer side of the ankle was made, the fragment picked up, the wound closed without drainage and the plaster cast applied. An excellent result was obtained.

H. W. MERRICK

Cotton, F. J., and Henderson, F. F. Results of Fractures of the Os Calcis. *Am J Orth Surg* 9 6, xiv, 300

The authors report the results obtained in 75 cases. The great majority were smashes of the os calcis received in falls on one or both heels from a height of from 5 to 40 feet. In general there was a "smash" below the weight-bearing vertical line of the tibia, running more or less, mostly less, vertically and various radiating lines running down and forward and backward. The heel was driven up and often was driven outward. The whole bone was compressed vertically and expanded laterally. There was often a pushing of fragments inward under the ankle, and almost uniformly a considerable pushing outward of bone-fragments, capped by the usually intact outer lamella of the os calcis under the external malleolus.

The authors believe that os-calcis fracture of the usual compression type is one of the most serious

lesions met with so far as future function is concerned. The prognosis as to use is as serious as fracture of the femur at the hip.

Late operations for correction are useful, but far from ideal in results. Palliative measures (plates, pads, braces, and shoe modifications) are usually useless. The authors recommend the Cotton reduction outlined in 908. PETER LEWIS.

Loonabery, B. F. Fracture of Os Calcis. *Surg Gynec & Obst* 9 6, xiii, 638

Fracture of the os calcis has been considered a rare condition. Recent statistics show that it forms about per cent of all fractures. In the past the condition has been largely unrecognized and treatment neglected. Diagnosis without X-ray examination is difficult. The cardinal points in diagnosis are:

History of injury (usually a fall from height landing on the feet)

Physical findings:

- (a) Heel broadened and everted
- (b) Absence of convexity on both sides of the Achilles tendon
- (c) Sinking of malleoli especially the internal one
- (d) Flattening of the longitudinal arch of the foot

(e) Ex. hyemesis

(f) Sometimes, repeat two

5. Pain

A. In old cases

- (1) Across front of instep
- (2) Under point of heel
- (3) Under external malleolus
- (4) In sole of foot

B. In recent cases

- (1) Diffused pain through heel and ankle aggravated by attempt to stand on foot by manipulation

4. Radiogram

No case of ankle injury should be finally diagnosed without this means.

Usually more than one line of fracture exists. Most frequently fracture begins in the concave articular facet of the os calcis where it articulates with the wedge-like articular facet of the astragalus. The portion of bone posterior to this point is usually driven upward and backward either in a single mass or broken by one or more lines. Usually there is considerable impaction. This displacement backward and upward produces flattening of the longitudinal arch of the foot. The fracture may be comminuted and occasionally may be compound. There may be a tear fracture at the insertion of the Achilles tendon or of the plantar tendon, or on the lateral aspect at the attachment of the calcaneofibular or lateral talocalcaneal ligament. There may be a simple line of fracture without displacement.

The results of treatment of this condition in the past have been poor. The condition is usually un-

recognized and neglected. In old cases palliative treatment is adopted such as arch supports for fallen instep pads under the heel for pain in the sole of the foot or operative procedures to remove spicules and projecting callus. In recent cases the normal contour of the bone should be restored. For tear fractures the fragments are sutured in position. Cases with backward and upward displacement of the posterior fragment (and these form a large majority of fractures of the os calcis) are reduced by passing a urethral sound in front of the Achilles tendon making strong downward traction while counter upward pressure is made on the anterior end of the bone in the sole of the foot. The fragments are held in position by severing the Achilles tendon and incising all in a plaster cast to the knee. While the cast is hardening the ball and heel of the foot are pulled toward each other making a high elevation in the arch of the foot. The cast is kept on for four weeks then removed and passive motion and massage used daily with hot foot soaks. The patient should be kept off his feet for ten weeks then arch supports are fitted in the shoes and he is gradually permitted to put weight on the foot while walking with crutches.

The disability usually lasts six months or more in recent cases properly treated. In unrecognized and neglected cases the disability lasts from six months to two years and may even become permanent.

Groves E. W. H. and Brown T. H. The Treatment of Gunshot Fractures. *Lancet* Lond. 916 cxc, 990

In a typical gunshot fracture the authors call attention to three main characteristics (1) great comminution with displacement (2) severe sepsis and (3) pain which becomes intolerable with movement.

The indications are directed to saving life and limb and to restoring function. To accomplish these results four things are necessary (1) immobilization for a long period (2) free drainage and frequent redressings (3) extension in a correct line (4) maintenance of both wound treatment and extension for a period which may be prolonged for several months. In addition the nearby joint should be immobilized so that the limb is in physiological rest and the flexors are relaxed. Massage and movement of the limb from an early period should be practiced.

Grossly infected wounds are frequent after fracture by bombs and shell fragments also by military rifle bullets at proximal ranges. They should be opened up freely at the earliest moment. Treatment should not be delayed for X-ray evidence if it is not at hand. Missiles and particles of clothing as well as all extraneous matter should be removed. Small punctured and penetrating wounds should be left alone with a simple dressing until further treatment can be given in a general hospital provided there is no evidence of infection.

In comminuted fractures the authors state with

positiveness that however freely they are opened up the bone fragments must be left *in situ*. There are only two exceptions to this rule (1) if the moving bone fragments (2) when the articular end of a bone is shattered all loose bone should be removed from the joint and (3) if a bit of bone is clearly devoid of all articular connection and lies in a septic wound it should be taken out.

Operative fixation of fragments is not recommended. If much minutely situated plating or wiring is useless and a mechanical impossibility and when the fracture is not comminuted it should be treated by extension. Barington's intraplate involution leads to non-union when the unit is already infected.

A very good description is given of the latest and best apparatus made of an hydraulic transmission reported in the *Medical and Surgical Description of the technique in the practice of immobilization*. L. T. A. L. C. 201

Darrach W. A Plea for the Immediate Reduction of Fractures. *Lancet* Lond. 916 cxv, 990

The author believes that the ill health which follows a fracture is due to the permanent disability and deformity and that a fracture with displacement should be considered as much an emergency as a late appendicitis or perforating ulcer. One should preferably have an X-ray first to assist in making an exact diagnosis but if not available manipulation is indicated without a early reduction is desirable and of sufficient advantage to offset the value of X-ray.

Open operation should be deferred until natural healing has an opportunity to marshall her forces and resistance and get the injured area entrenched behind a zone of infiltration.

Immediate reduction of fractures with displacement results in easier and more accurate apposition less pain less swelling less reparative tissue formation and a more rapid solid bony union.

H. W. MEYERDIN

Gallie W. E. Open Operation for Fractures. *Can. J. Med. Sci.* 96 cxxx, 63

Gallie in his article makes a plea for the use of boiled bone for plating fractures. His experiments show conclusively that when any form of transplant is used death of the transplant follows with subsequent replacement of the dead bone by new formed bone which is deposited along the ingrowing capillaries. Since this is true the author believes that boiled bone plate can be used more successfully than autogenous grafts as they can be prepared beforehand.

Gallie uses a plate made from beef bone curved in transverse section and thicker in the middle than elsewhere. For fastening the plate screws of bone are used these are cut on a lathe. In cutting the hole for the screw a tap smaller than the screw is used, into the thread thus cut a polished steel screw is driven this cuts a thread and hardens it by com-

pressure so that when the bone screw is put in it does not crumble.

When the bone screw is turned a short stem is left attached to the head, this is tapered and squared to fit into a chuck made like a clock key by which the screw is driven home. The stem is turned down thin at its junction with the head so that it can be broken off after the screw is in place.

Gallo also describes a bone holding clamp for retaining the fragments in place this can be better appreciated by reading the original article.

FRANK D. DICKSON

SURGERY OF THE BONES, JOINTS, ETC.

Walther C. Repair of a Branch of the Trapezius and Splenius with a Clavicle Adhering to the Cervical Vertebrae (Réparation d'une branche du trapèze et du splénius avec clavicle adhérent à la colonne cervicale). *Bull. et mém. Soc. de chir. de Par.* 9 6 xiii, 585.

The patient reported by Walther was injured by a gunshot and showed a deep clavicle about the size of a five franc piece adhering to the cervical vertebrae at the crest of the left half of the sixth and seventh cervical vertebrae. The trapezius, splenius, and first layers of the rhomboid had been sectioned by the projectile.

It was impossible to elevate the shoulder and pain radiated along the spine. Walther excised the clavicle, freshened the muscles and sutured them which not only resulted in the correction of the deformity but left a condition which as far as construction was concerned, did not differ from the opposite side.

W. A. BAKERMAN

Linberger Hypodermic Treatment of Joint Injuries (Ueber die angedehnte Behandlung bei Gelenkverletzungen). *Münch. med. Wochenschr.* 9 6 liii, 33.

Linberger reports the details of 8 cases of severe injuries of the knee-joint treated by Bier's method of continuous hyperemia which was found practicable in field surgery and requires no more time than other procedures for severe wounds. Of the 8 cases 7 were cured.

This method is particularly useful in knee joint gunshot injuries which are almost always infected wounds. It obviates and checks the results of infection and thus renders major operations unnecessary. Fever abates soon after the beginning of treatment and pain is usually decreased within twenty-four to thirty-six hours. The end functional results were good.

W. A. BAKERMAN

Mouchet, A. Treatment of Fistulous Ostitis by the Polyvalent Serum of Lecithine and Vallée (Le traitement des ostéites fistuleuses par le sérum polyvalent de Lécithine et Vallée). *Bull. et mém. Soc. de chir. de Par.* 9 6 li, 598.

The author reports the moderately satisfactory results which he has observed in the treatment of fistulous ostitis by the serum of Lecithine and Vallée. The use of this method offers doubtful advantages and may occasion great danger.

The author believes that the majority of ostitis should be treated surgically. The mechanical action of the serum which would aid in the elimination of the sequestrum is manifested only when no surgical treatment has been instituted.

The calcification obtained after the use of serumized dressings is not always durable. Serotherapy does not always suffice to bring about recovery and then surgical interference has to be adopted under the least favorable conditions. Moreover the employment of the serum may give rise to accidents, lymphangitis, erysipelas, and abundant and fetid suppurations from the tract of the ostitis.

Serum may be of use in the treatment of the soft parts and in cases of superficial ostitis but it should be used with extreme caution. W. A. BAKERMAN.

Armstrong, H. M. and G. L. Jr. Treatment of Injuries in the Vicinity of the Elbow-Joint. *Ann. Surg. Phila.* 9 6 liii, 596.

The authors review the anatomy of the elbow joint and call attention to the gravity and frequency of injuries in this region. They divide elbow joint injuries into

Fractures of the lower end of the humerus (1) supracondylar fracture (more or less transverse of the shaft above the condyles) (2) T or Y shaped fractures (3) epiphyseal separation (4) fractures of the external or internal condyles and epicondyles

5 Lesions of the radius and ulna (1) dislocation backward of the radius and ulna (2) fracture of the upper third of the ulna, with or without dislocation forward of the radius (3) dislocation forward of the upper end of the radius (4) fracture of the olecranon process of the ulna (5) fracture of the neck or head of the radius (6) subluxation of the head of the radius (7) fracture of the coronoid process of the ulna.

3 Simple sprains of the elbow

Treatment and surgery of these conditions are discussed. Attention is called to the fact that frequently dressings are responsible for stiffness following joint injuries, and that the best results are obtained by dressings in acute flexion as soon as the acute symptoms have subsided, during which time they are dressed in extension. Passive motion is advised when due to prolonged immobilization, adhesions, etc., though many able authorities advise to the contrary.

Ankylosis due to excessive callus or displaced fragments demand operation and massage. The use of splints, etc., is advised against.

H. W. MEXTERO.

Hardouin, P. Resections of the Elbow in War Surgery: Functional End Results (Observations de résections d'os en chirurgie de guerre: résultats fonctionnels). *Bull. et mém. Soc. de chir. de Par.* 19 6 xiii, 163.

The 51 elbow resections reported by Hardouin are divided into 3 groups (1) primitive resections

(within 24 hours) 19 (2) secondary resections with drainage 25 (3) late secondary orthopedic resections, 7

The first group gave the worst results. In 9 cases there was no voluntary improvement. 5 are ankylosed, 2 semi-ankylosed, 3 with limited flexion.

The second group gave 3 good results with extended strong movement, 4 with limited flexion, 7 ankyloses (5 with half extension or somewhat more, 2 with bad extension), 6 with no spontaneous movement, 5 with defective flexion. Of the 25 cases 7 arms are good or fairly good, 5 are ankylosed and in 13 the arm can give no real service.

In the third group among the 7 cases 4 showed good results, 1 moderate, and 2 bad.

Despite the poor functional results the author thinks that resection of the elbow with drainage is an operation of necessity when the life of the patient or the limb is endangered.

W. A. BRENNAN

Legg, A. T. and Ober, F. R. Tendon Transplantation. *Internat. M. J.* 1916 xliii 333

The authors' present conclusions are drawn from 100 cases of tendon transplantation at the Children's Hospital, Boston, during the five years previous to 1914. Transplantations at the ankle alone were considered.

Under general considerations the authors call attention to the proper muscle balance being sustained following transplantation, the inadvisability of waiting too long, probably two years after the disease would be best because of the weakness following fixation, etc., with braces. Actual paralysis must be determined as muscles may appear to be paralyzed but are only apparently so from overstretching, etc. Leverage and mechanical possibility must be considered.

Operative considerations favor correction of deformity, first, the tendon-transplantation making the wound away from the course of the tendon and inserting it well into the bone after passing under fascia, fat and annular ligaments. Insertion with out tension and careful closure of the tissue overlying the tendon are advised to prevent adhesions.

Post-operative treatment consists of plaster of Paris in an overcorrected position, light massage at the end of three weeks, wearing of a plaster cast for three months and a brace two to four months.

Causes of failure are faulty technique, poor selection of cases, and inefficient after-care. Too long wearing of braces is warned against. Six months' time is sufficient.

H. W. MEYERDINO

Jones, R.: Notes on Military Orthopedics. Suture of Nerves, and Alternative Methods of Treatment by Transplantation of Tendon. *Brit. M. J.* 1916 l, 63 679.

The author calls attention to the proper treatment of nerve injuries causing limb disability. His wide experience before and during the war makes his observations most valuable. In his opening paragraph he dwells upon the orthopedic features in the

treatment of nerve injuries, as nerve injuries rarely occur without damage to the surrounding structures—bone, tendon, muscle and skin.

In suture of the nerves the following points should be observed:

1 The correction of contracture of the skin or muscle and all the anatomical constituents from the skin to the bone on the concave aspect—that is to say on the abnormal direction the contracture takes.

2 When possible the freeing of joints from all adhesions and the restoration of the mobility of the joint in all cases where ankylosis of the joint is threatened.

3 The maintenance of the paralyzed muscles in a position of relaxation throughout the period of recovery.

4 The practice of massage during recovery but without once allowing the relaxed muscle to be stretched.

He lays especial stress upon the relaxation of the muscle and has found that this elemental principle is often neglected. He says the most skillful operation performed on the most suitable case will prove a fiasco unless the affected muscles are kept continuously relaxed until recovery takes place.

He recalls his previous statement that though poliomyelitis may permanently destroy the motor cells of the anterior horns of the gray matter and thus forever render the muscles dependent upon them useless, this however has seldom been the case and clinical experience has shown complete paralysis with complete recovery and many partial recoveries, thus proving that the motor-cells thus concerned suffered only temporary injury.

The difference between an overstretched and a paralyzed muscle must be recognized and this can only be done by putting it in a position of relaxation and giving it prolonged rest for at least six months. Although many of the principles are applicable to gunshot wounds there is a limit to conservative methods, and in cases presenting a promise of success nerve-suture is advised. The author states that his experience in tendon transplantation in poliomyelitis has been of great value to him in caring for gunshot wounds.

H. W. MEYERDINO

Quénou E. Partial Amputations of the Foot for Gunshot Wounds of War (Note sur les amputations partielles du pied dans les plaies par projectiles de guerre). *B. H. et Mém. Soc. de chir. d'Paris* 9 6 xli 538.

Injuries to the foot by gunshot wounds are comparatively rare. In the statistics of Nové-Josserand, Gourdon and others in 2,516 amputations there were only 110 partial amputations of the foot, and a great many of these were on account of frost bite.

Quénou thinks that in injuries to the foot as in those of the hand, even when the injury is severe there should be no haste to amputate and when amputation is necessary it should be done in healthy

tissue. If there is no appearance of infection, the general rules of surgery should be followed i.e. removal of the projectile and cleansing the wound. If the operation is done early with arrest of the projectile in the tissues, reunion by first intention may be obtained even in articular wounds with a rapid cicatrization and return of the functions of the foot. If there is infection and the joints are suppurative, the phlegmonous foci must be incised and evacuated. If drainage of the articulation is difficult amputation may have to be done but this should be confined to plane section in the infected articulation.

The final plastic restoration should be delayed for several weeks when the field of operation is in a generally healthy condition. This will give opportunity for an economic operation. As much of the calcaneum as possible should be preserved.

Protopopoff operation, either modified or not appears to be the most desirable. W. A. BEAVER

ORTHOPEDICS IN GENERAL

Painter, C. F. Hallux valgus. *Boston M J* 9 6 April 636.

The etiology and treatment of hallux valgus is here taken up. Hallux valgus is merely an outward deviation of the great toe accompanied usually by bursa-formation, and more or less painful and disabling static disturbances.

Hallux valgus is nearly always accompanied by a relaxed anterior arch with its flat forefoot callus formation, and general discomfort. It is essentially a shoe deformity, short and pointed shoes giving the greatest number of cases.

Pathologically hallux valgus is not an arthritis at all shows no thickening of the metatarsal

phalanx, but does exhibit an atrophy or erosion of the articulating head of the metatarsal.

For operative treatment Painter recommends the old Ilizarov operation removing the metatarsal head, and advises the use of a metal splint to prevent riding up of the phalanx on the metatarsal. He condemns the use of a ring in the bursa between the metatarsal and phalanx. R. G. PACKARD

Cross, C. Golfer Foot. *Med P* 9 6 April, 636

Golfer foot is new name for the old condition of metatarsalgia and as defined by Cross, is a distortion downwards of the heads of the second, third, and fourth metatarsals or any one of them. In the golfer this condition is due to the fact that when making for instance a right handed drive, the player throws most of the body weight over the anterior portion of the left foot so the foot has been elevated with the upswing. This weight is distributed mostly to the outer half of the arch, including the third, fourth and fifth metatarsal heads, and strain may be produced. This condition of relaxation or rupture of the ligaments of the anterior metatarsal arch, may also occur in any overused foot.

The symptoms include first slight discomfort at the base of the third or fourth toe, slight swelling on the dorsal surface, pain on pressure and a feeling of irritability or stinging. Physical signs are practically equal. Treatment consists in correcting the arch by the application of dry heat, holding up the arch by some flexible support, exercising the feet nightly and reducing the acute inflammation by a wet dressing of magnesium sulphate. The patient should trim his toes in more should not change suddenly from high to low heels, and should wear shoes not too short. R. C. PACKARD

SURGERY OF THE SPINAL COLUMN AND CORD

Castex, M. R. Vertebral Metastatic Carcinoma Primary in the Breast (Carcinoma cribral metastático por primitivo de la mama). *Pra* 54 *Med Argent* 9 6 April, 636

The author reports a case in a woman of 4. The history showed that in October 1915, the left breast had been excised on account of tumor. Examination in February 1916, showed the vertebral column grossly deformed, dorsolumbar kyphosis, movements of extension flexion and lateroflexion, considerably reduced and painful, pressure very painful from the second dorsal to the sacrum, apophyseal deviation in all the zone of the kyphosis, intense lumbago on both sides of the column in the dorsolumbar zone, bland elastic, and very painful.

Three possible genetic causes for the spondylitis, leuc, tuberculous, or neoplasm, are considered. The first two Castex rules out for reasons given and

deduced from the symptomatology. He thinks the mode of onset the morbid course, and the actual symptoms fully correspond to a vertebral carcinoma process. The fact that the patient had already had neoplasm of the left breast is significant and although it may be objected that the spondylitis might have existed prior to the neoplasm yet the author thinks that this in the history clearly prove that this was the case.

Vertebral carcinoma is never primary it is always secondary metastatic. The observations on record of primary carcinoma do not stand before anatomopathologic criticism and they are all shown to be endothelioma or primary sarcoma. Vertebral metastatic cancer always corresponds to the primary type from the histological viewpoint. It is much more frequent in women than in men, and corresponds with cases of mammary carcinoma. The author is aware of only one case of vertebral

carcinoma in which the uterus was the prime focus. In similar cases in man the prime focus is in the prostate or bronchii.

The point of incidence in the vertebral body is usually the spongy tissue and it develops most commonly into osteoclastic carcinoma but it may take the osteoplastic form. The dorsal and lumbar regions are the most frequently attacked and the process usually extends to many vertebrae.

The author points out that a woman operated upon for a mammary cancer many months or years later show nervous phenomena which are a consequence of the primary neoplasm. He refers to such cases and he thinks that the pathology of vertebral carcinoma can explain all the spondylitic phenomena.

The prognosis in this as in other advanced cases is fatal. No reliance can be placed on arsenical radio-activity or colloidal preparations which have always failed in such a condition. W. A. BREWSTER.

Schachner, A.: Injuries of the Spinal Cord with Report of Gunshot Injury of the Cord at the Fourth Cervical Vertebra and Successful Removal of Projectile. *S. G. G. Obst.* 66, 221-266.

The case reported was that of a boy shot with a 2-calibre long projectile fired from a rifle. It lodged in the posterior columns of the cord and was successfully removed from the cord at the level of the fourth cervical vertebra. In this paper dealing with injuries of the spinal cord the author emphasizes the following points:

While a carefully prepared set of radiographs stereoscopically studied will supply valuable data as to the course of the projectile and the probable nature of the spinal injury from which valuable con-

clusions as to the possible existence and probable extent of cord injury can be drawn it is pardonable to emphasize the warning that the diagnosis however carefully made is frequently misleading.

The term concussion with regard to the cord which there is considerable difference of opinion in being accepted by some and rejected by others. The term may be said to mean the impairment of the functions with which the spinal tract and anterior horns are concerned.

If a hematoma has occurred a laminectomy will remove the pressure within the spinal canal.

Hematomyelia is a pathological condition of the spinal cord which is not rigid and a drainage. The term and other terms are estimated as to their frequency. Hematomyelia is a condition of the spinal cord in which the white matter is completely supported in the gray matter. As the gray matter is most predominant in the cervical region it is the most favorable region for its occurrence.

The Röntgen-ray spinal puncture and a careful neurologic study is the diagnostic triad upon which we are dependent.

It is difficult to avoid the conclusion that an accurate estimate of the cord destruction is frequently impossible and if this fairly represents the status it is not proper to lay down the axioms. When in doubt explore.

If modern surgery in lay claim to no a hie ment it the elimination of doubt through cautious exploration and the fact that some exploration can be shown to be useless or even a few fatal does not in the author's judgment invalidate the broad application of the rule.

SURGERY OF THE NERVOUS SYSTEM

Sicaud, J. A. and Dambrin, C.: Nerve-Sutures (Sutures nerveuses). *Bull. et mém. Soc. d'hist. nat. P.* 1916, xxxii, 96.

In reviewing the observed cases of nerve suture for the past 15 months it appears that the classic techniques followed have not fulfilled the expectations held out and that other operative methods must be sought to give better results.

Experimental operative interventions made prior to the war — clear sections with a minimum of suppuration — are very different from those met with resulting from projectiles. The lesion is more extended fusion is distant in the nerve trunk the cicatrix is hard and retractable formed at the expense of tissue a long time suppurative and it may even be fibrous or cartilaginous in consistency. The operator may attempt a partial resection and endeavor to make an end-to-end suture of such altered tissues which is sure to be a therapeutic

failure or if a large resection is attempted end-to-end suture is not utilizable. In such case suture *par doublement* may be tried but this is doomed to total failure. Unfortunately the cases are rare in which the extent of the nerve injury is so reduced that it is seen within the operative field and that the ends may be united directly to other nerve fascicles with preservation of the surrounding nourishing tissue. This when it happens is the method of choice and offers the best chances of recovery.

After having performed a large number of nerve sutures by different classic methods the authors are led to believe that end-to-end suture after strict resection of all fibrous parts remains the best method but that whenever such suture is impossible the method of choice is the nerve-graft which may be either by heterograft or autograft.

The authors describe their technique of nerve

grafting. They have performed 11 such operations since December 1915 but it is too early for an opinion as to the results.

Gosset, who submitted this report, stated that according to figures published in 1915 by Sicaud, the actual number of cases in which the authors had performed nerve-suture was 37. There appears to have been only 1 success in the series so there was nearly 100 per cent of failures. Personally he has made 353 interventions for lesions of peripheral nerves during the war 126 nerve-sutures, and 25

nerve-grafts. Referring only to cases before January 1915, of 2 cases of complete interruptions, 6 were treated by excision and end-to-end suture. In all there was functional amelioration and in 5 there was a return of mobility. Of the other 6 cases 2 were treated by *dédoublément*. In one of these there is partial restoration of motion and sensation. The other 4 cases were treated by liberation. In each case the result was nil. The end-results of some of his graft cases are encouraging and he will report on them. W. A. BRECKMAN.

MISCELLANEOUS

CLINICAL ENTITIES—TUMORS, ULCERS, ABSCESSSES, ETC.

Roffo, A., and Qallo, N. Contribution to the Chemical Study of Tumors (Contribución al estudio del quimismo de los tumores). *Prespa. med. Argent.* 9 6 No. 12, 378.

The experiments were carried out on rats.

In a tumor weighing 36.256 gm. the total solid substances were 14.05 per cent, while the total of water found was 85.95 per cent. The amount of protein found was 56.5 per cent of the dry substance, organic matter and minerals 3.6 per cent neutral 1 is 10 per cent phosphates 8.7 per cent the minute rest was found composed of phosphorus and nitrogen.

From the results of careful experimentation, the authors draw the following conclusions:

1. The chemical composition of a tumor is constant.

2. The globular composition is constant and the same in carcinoma as in sarcoma, artificially produced in the rat. RAOU L. VIGORAN.

Villa, G. T. Malignant Pustule Treated by Bac. celli's Method (Un caso de pustula maligna tratado por el método de Bacelli). *Rep. de med. y cir. Bogotá*, 916, VII, 304.

A small puriginous void in the left malar region of a child of 10 existed after local treatment, including cauterization. The scar became surrounded by small pustules, there was considerable edema, and the neck ganglia tumefied and painful.

The child was removed to the hospital and an intravenous injection of 5 cubic centimeters of bichloride of mercury solution in artificial serum 1:1000 was made. Four milligrams of mercury were used. The treatment consisted in the use of compressions on the face and chlorate of potash gargle. Within a few days all symptoms were subsiding. When last seen there was only a scar the edema had disappeared, and the ganglia were no longer apparent. W. A. BRECKMAN.

Simmonds. Cachexia of Hypophyseary Origin (Ueber Kachexie hypophysären Ursprungs). *Monatsh. med. Wchnsch.* 9 6 XLIII 243.

About two years ago Simmonds published the account of a case of puzzling cachexia which terminated in death, and in which the cause was deemed to be an embolic process of the hypophysis.

The case which he now reports is that of a man of 53 who for more than a year showed anemic and other symptoms. An occult cancer was suspected. Autopsy showed that apart from terminal pneumonia there was a hypophyseary tumor somewhat larger than a hazelnut which had almost completely destroyed both hypophyseary lobes. In the absence of other explanation the cachexia can be explained only by the hypophyseary alterations. There was no sign of a renegade pituitary body, only the basophilic adenoma of the hypophysis polyuria and adiposis were lacking but on the other hand genital atrophy and cessation of spermatid secretion and fall of pudendal hair were noted.

Simmonds also refers to a third case of hypophyseary cachexia in a girl of 9 with a basophilic adenoma of the hypophysis, a temporary polyuria being the only clinical symptoms. W. A. BRECKMAN.

BLOOD

Beuttl, M. Importance of the Lymphocytosis of the Blood (Importancia de la linfocitosis de la sangre). *Rev. Arg. med. Argent.* 916, XII 54.

Beuttl thinks that lymphocytosis *per se* does not call for specific treatment. In a syphilitic patient without symptoms, with the Wassermann and Nonne-Apert reactions negative, but with lymphocytosis in the blood nothing can be deduced from this sign. In the case of a patient without specific symptoms showing neither globulinuria, nor cellular modification in the cephalorachidian fluid, and the two Wassermann reactions negative and with lymphocytosis alone in the blood, this picture is not sufficient to affirm syphilis. W. A. BRECKMAN.

Friedmann M: Intravenous Continuous Infusion at the Front (Ueber Intravenöse Dauerinfusion im Felde) *München med Wkchr* 1916 lvi 553

Friedmann cites Garré Nowakowski and others whose experience is that subcutaneous infusion of salt solution fails in war surgery at the front. His own experience is similar and he has given up that method and used continuous intravenous drip infusion for more than a year and has obtained much better results. The method is illustrated by citing a case of severe gluteal region grenade wound the patient blanched and almost pulseless. The cubital vein is at once opened there being no necessity for anesthesia. A glass cannula is sutured into the vein and the infusion dripping is regulated by means of a Martin glass ball apparatus. When the pulse is felt the drip is regulated to 200 per minute. The operation is then proceeded with.

The rate of drip is varied from 30 to 200 per minute after the operation according to the condition of the pulse and diagen stropanthin or adrenalin can be added or isotonic sugar solution may be used instead of the saline. Not more than four to five liters of water should be used in from twelve to twenty hours. W. A. BRENNAN

Miller G I: Blood Transfusion *Long Island M J* 1916 189

In the hope of finding a method of performing blood transfusion which would overcome all objections to the excellent syringe method of Lindeman the author devised a valve, which consists of a central body a cylinder 1.5 in. long and 0.5 in. in diameter with two arms extending in opposite directions. On the upper surface is a thumbscrew arrangement which slides back and forth on an internal fitting which has two grooves of the same size as the lumen in each arm. From the under surface of the central body a cylindrical stem just large enough to receive the tip of a Record syringe projects downward one inch.

The two arms are connected to pieces of 12 F rubber tubing 3 in. long. In the distal end of each tube a metal tube is inserted, which fits the cannula and needle used for transfusion. By moving the thumbscrew back and forth the current can be directed into either arm.

To overcome difficulties encountered in handling and steadying certain cannulae on the market the author has devised an instrument which is composed of three parts: cannula, hollow needle and obturator. The needle and obturator fit snugly and telescope into the cannula. The obturator and cannula are of equal length 2½ in. The hollow needle is one half inch longer and is slightly grooved and bevelled to a fine point. Three-quarters of an inch from its distal end the cannula is encircled by two rings. The space between is just wide enough to receive a suture which is temporarily placed by being passed through the

skin to hold the cannula in position preventing it from being shoved back and forth during the aspiration and injection of blood.

The cannula, telescoped by the needle bevelled point upward is pushed through the skin and into the lumen of the vein for about a quarter inch and the needle is withdrawn for a short distance to prevent puncturing the vessel wall. The cannula is then driven into the lumen of the vein until the ring on the cannula meets the skin. When blood is observed coming through the needle the needle is withdrawn and if the cannula is not against the wall of the vein the blood will flow freely. The obturator is then inserted and a suture passed through the skin and tied between the two rings of the cannula to prevent it from slipping. If the blood does not flow freely through the cannula it is withdrawn slowly a quarter inch or so.

With the donor and recipient cannulae in position the operator removes the obturators and adjusts the metal tip of the rubber tubing to the cannulae to be easily. A 10-ccm. Record syringe is filled with warm normal saline and air forced from both arms of the valve before adjusting it to the cannulae. The thumbscrew of the valve is then pushed in the direction of the donor's arm the piston is drawn very slowly and the syringe filled with blood. The thumbscrew is then changed toward the recipient's arm and the syringe emptied rapidly of blood. The operator continues to alternate the direction of the thumb screw filling and emptying the syringe without disconnecting it from the valve, until the desired amount of blood has been transfused.

ALBERT EHLENFRIED

Carter W S: An Experimental Study of the Use of Sodium Citrate in the Transfusion of Blood by Direct and Indirect Methods *S Ark M J* 1916 14, 427

Carter's experiments were upon dogs. His apparatus consisted of an ordinary pharmacist's percolator of 300 ccm capacity. This was calibrated and a perforated rubber stopper was fitted into each end. The stopper at the bottom end had a Y-shaped glass tube drawn out to form two cannulae inserted into it. The upper stopper had a bent piece of glass tubing inserted into it which served to connect the cylinder with two pressure bottles. The pressure bottles were used to control the pressure in the cylinder.

At the beginning of each transfusion 50 ccm of a 2 per cent solution of sodium citrate was put into the cylinder and the blood was drawn in by lowering the pressure bottle. For the first and second groups a uniform negative pressure was used when filling the container and a uniform positive pressure in emptying it. It became apparent that the most important factor was the length of time the blood was kept out of the body. So in the third group the blood was kept in the cylinder a uniform period of time by varying the pressure. It was found that the blood should not

be kept out of the body more than on and one-half minutes at the most.

The solution of sodium citrate was compared with physiological salt solution, with Ringer's solution, and with a solution of hirudin.

In the experiments in which sodium citrate was used in the indirect method the blood was allowed to flow through a paraffined cannula into a flask containing 25 ccm. of a per cent sodium citrate solution until the flask was filled up to the 50 ccm. mark. The citrated blood was filtered through several layers of sterile gauze wet with physiological salt solution before it was introduced into the recipient's vein. Small clots were frequently found on the gauze showing the necessity for this precaution.

It was found to be very important to have cannula large enough to give a free flow from the donor, thus avoiding delayed coagulation which occurred in the citrated blood after it had been filtered through gauze in three cases in which the flow was slow.

In Carter's experiments he found

1. That sodium citrate is a satisfactory anticoagulant when used in the cylinder of direct transfusion in a 2 per cent solution.

2. That transfusion can be continued from 5 to 3 times longer with a 2 per cent citrate solution than with a physiological solution.

3. That a solution of sodium citrate is as efficient as a solution of hirudin, as shown by the amount of blood transfused or by the time of transfusion.

4. That sodium citrate does not lessen the coagulability of the blood and is not toxic in the amount used.

5. That the coagulability of the blood is temporarily increased immediately after transfusion in which sodium citrate is used.

6. That the lethal dose of sodium citrate to dogs is about 1 gram per kilogram of body weight when dilute solutions are injected and that a concentrated solution the dose is not more than 0.5 gram per kilogram.

7. That a 0.1 or 0.3 per cent solution of sodium citrate is sufficient to prevent coagulation and does not have any toxic effect in the amount used for indirect transfusion in man. J. W. TAYLOR

BLOOD AND LYMPH VESSELS

Soubbotitch V. Traumatic Aneurysms (Aneurysms traumatiques). *Bull. et mem. Soc. d. k. de Par.* 1906, 2nd, 698.

Soubbotitch of Belgrade gives details of vascular surgery performed by him during the Serbian wars of 1902 and 1903 and also during the present war.

In all the author has operated upon 69 cases of traumatic aneurysm. The details of 45 of these were left behind on the retreat of the Serbian Army from Nish, and these, if available, will be published later. The present report therefore deals with 24 operated cases only. In these 16 important vessels were injured: 120 arteries and 32 veins.

The operations on the 61 comprised 107 ligatures—93 arteries, 14 veins, 30 angiorrhaphies—32 arteries, 18 veins—29 being partial and 3 total. 43 had operations (aneurysmorrhaphy).

The operative results are as follows:

In 7 arterial aneurysms treated by ligature, there were 56 recoveries. Improved 8 cases of gangrene. 8 deaths.

In 8 arteriovenous aneurysms treated by ligature there were 14 recoveries. Case of gangrene. 3 deaths.

In 23 angiorrhaphies for aneurysms there were 8 recoveries, 5 failures of which 1 died.

Of 9 arteriovenous phlebostenic venous aneurysms there were 5 recoveries, 3 deaths, 1 failure, and 1 unknown.

Of 4 Malas operations 1 recovered.

Post-operative gangrene developed in 6 cases. In 9 of these amputation was performed and the cases all recovered. Amputation was refused in the tenth case. Of the gangrene cases 3 occurred after ligature, 1 after angiorrhaphy.

In all there were 13 deaths, 9 after ligatures and 4 after surgery. The causes of death were aneurysm, 4 cases, secondary hemorrhage, 3 cases, pneumonia, 1 case, septicaemia, 1 case, embolism, 1 case, 3 cases.

The full details are given in the tabular statement.

As regards the Carrel operation (angiorrhaphy) in war the author says that owing to insufficient experience with it they soon came to the conclusion that in the case of this operation should be successful the case must be accepted. In his opinion the Malas operation is an excellent one and is recommended. Finally he states that experience shows that the plasticity of the healthy and non-infected vascular walls is much greater than he believed and that an injury to the endothelium can often be sutured without hemorrhage. Such sutures can offer a guarantee against secondary hemorrhage.

W. A. BRYCE

Begouin, P. and Moulins R. Arteriovenous Aneurysm of the Axillary Artery (Aneurysme artérioveineux de l'artère axillaire). *J. de med. d. Paris.* 1906, 1, 76.

The patient in this case was wounded early in August by November 3, the date of the operation, the aneurysm had the aspect of a fusiform mass occupying the summit of the axilla was pulsatile and had double bruit which was propagated in the pectoral region. The hand was cold, discolored and slightly oedematous. The operation was long and tedious. The artery and vein were ligated above and below the aneurysm prior to its excision. The compression of the subclavian artery on the first rib did not interrupt the arterial flow. After including the pectoralis major and axillary artery were temporarily ligated. The aneurysm included 3 cm. of artery and 6 cm. of vein. After excision the circulation was re-established in the limb in better mechanical condition than before the operation.

Attention is called to what the authors term the collateral sign i.e. when the circulation has attained a certain value, examination of the collateral vessels will disclose very clear pulsations over ordinarily non-pulsatile arteries. In this case the external mammary and the subscapular arteries were distinctly pulsatile. This sign when observed is a valuable indication for intervention and it is a symptom which argues well for a favorable prognosis.

Séjournet does not favor compression in wounds of veins because it does not assure drainage and favors infection of the wound while allowing the risk of a secondary hemorrhage. He thinks ligation of a large vessel by bringing the return circulation to an abrupt stop in a limb exposed to infection compromises its vitality. Hence his preference is for lateral suture which only narrows the caliber slightly and re-establishes the circulation.

W. A. BRENNAN

Graf P 1 Experience with Vascular Injuries (Erfahrungen bei Gefäßverletzungen) *Beit. kl. Chir.* 916 xiviii 53

The author gives his experiences derived from 58 vascular wounds observed during the fighting around Warsaw.

In these 58 cases, 62 interventions were made three times arrest of hemorrhage in dying men 43 ligatures 5 amputations of limbs 8 suturings 3 tamponades under narcosis. The general mortality was 25 per cent. The carotid externa was ligated six times the carotid interna once and the maxillaris externa twice. Tamponade was absolutely necessary in one case. There were 15 ligatures and 3 suturings of the subclavian, brachial and cubitalis for arm wounds.

In the leg region 30 interventions were made for 29 injuries 23 ligatures — 5 amputations for infection 5 vessel suturings 2 tamponades under narcosis. Of these interventions 16 were on the femoralis — 11 ligatures 6 suturings. In 4 out of 5 interventions on the popliteal infection was already manifest and in the fifth case the patient died of secondary hemorrhage after a couple of weeks. In the tibialis ligation generally stopped the hemorrhage. In one of these cases amputation was found necessary and the patient died after a few days owing to loss of blood from the stump.

Eight arterial suturings were done without any subsequent secondary hemorrhage, infection or death. The author's experience leads him to think that vascular injuries coming to the field surgeon are under all circumstances to be considered as life endangering. In only the minority can a smooth infection free encapsulation of the blood outlet be obtained and by the development of aneurysms bleeding may continue for weeks. Every secondary hemorrhage even if slight makes an

opening up of the bullet tract imperative. This should be done even if the bleeding ceases. Later hemorrhages may be expected with certainty. Therefore it is always best under narcosis to lay bare the large vessels in suspected and particularly in infected cases.

For ligation of the vessels is the best procedure in even slightly infected cases may be sutured when the external wound is well trimmed. The vessel must be clearly separated away from the cavity by muscle suturing.

Ligation of the larger vessels must be kept up for two or three weeks especially when the collateral blood flow can be regular and checked by a proper position of the limb.

Hyperemia and the procedure of Moszkowicz are adaptable when there is a question of the development of collateral circulation.

POISONS

Baxby Localized Tetanus (D. 161 localisé)
Bull. Acad. d. Méd. P. R. 1016 lxx 594

When tetanus develops it usually attacks the whole muscular system. But some cases have been noted in which it has attacked only one part of the body leaving the head free. This type has been designated as localized tetanus.

The author has found a case which he believes answers this description in a soldier who had the left leg amputated. Antitetanic serum was injected six hours after injury. The wound suppurated and there was some fever. All the usual symptoms of tetanus developed trismus dysphagia sardonic laughter pain fever and profuse perspiration and antitetanic treatment was instituted with an immediate cessation of most of the symptoms. Bacterial culture showed the pyocyanus only and inoculation proved negative. No tetanus spores were discovered.

The author while admitting the possibility of local tetanus thinks it is difficult to diagnose as tetanus these cases in which more or less extensive contractures are observed with a particularly painful infected wound.

W. A. BRENNAN

Goadby K. The Treatment of Tetanus. P. 1
Lancet Lond. 9 6 cvl 526

The treatment of tetanus is divisible into two main categories prophylactic treatment and curative treatment.

The prophylactic treatment aims to accomplish three cardinal points (1) to prevent the growth of the tetanus bacillus in the wound itself (2) to neutralize any poison formed by the organism directly it is formed and before it can attack the nerve tissues (3) to cause as little local disturbance as possible to the parts infected by the tetanus organism especially nerve trunks.

1 To prevent the growth of the tetanus bacillus it must be always kept in mind that the organism

is a strict anaerobe, and therefore free oxygen prevents its development. Wounds contaminated with earth, especially contused, punctured, or lacerated wounds, should be freely exposed to the air protected only by very thin coverings. Oxygen in the form of peroxide of hydrogen should be used freely and waste dressings must be burned at once.

To neutralize any poison formed before it becomes absorbed by the nerve tissue, a prophylactic dose of antitetanus serum should be given as soon as practicable after the injury and before any extensive wound cleaning is performed. It should be administered subcutaneously in a dose of 500 U S A. units. Since this procedure has been adopted, very few cases of tetanus have been recorded from the front.

3. Adequate and convincing experiments have proved that the tetanus toxin finds its way along the perineural lymph-channels into the central nervous system. As little local disturbance of the wound as possible is therefore indicated if any premonitory symptoms of tetanus have appeared, such as rigidity or local spasm of muscles in the immediate neighborhood of the wound, or an occasional symptom, general rheumatic pains. When definite tetanic symptoms have appeared it is highly dangerous to amputate or perform any operation which opens up the nerve trunks anywhere near the wound.

The chief points in the treatment of established tetanus are:

1. The early recognition of the prodromal symptoms. Lockjaw is nearly always a late symptom.

2. To neutralize the poison in the nerves and blood stream, and to extract such as has already become absorbed by the central nervous system.

3. To keep the patient strength up until the neutralization of the poison is effected by the natural defensive powers of the body aided by the administration of the appropriate antitoxin.

Chief among the early symptoms are local muscular rigidity and fibrillar twitchings sometimes the latter are noticed by the patient himself. In a severe and extensive wound, rigidity due to tetanus spasm may be mistaken for traumatic swelling, but the rigidity in tetanus is usually confined to muscle groups, such, for instance, as the right half of the anterior abdominal wall in a wound of the right groin, the left rectus and the external oblique being flaccid the deltoid and triceps in a wound of the upper arm.

The most important clinical treatment of tetanus is the administration of the specific antitoxin. The researches of Park and Biggs have shown the value of the intrathecal route for the administration of tetanus antiserum.

There is little advantage in administering tetanus antitoxin intravenously as well as intrathecally and from Park's experiments it appears doubtful if tetanus antitoxin enters the cerebrospinal fluid from the blood. When tetanic spasms are established,

intrathecal injection of tetanus antitoxin should be performed.

Fifteen to twenty ccm. of cerebrospinal fluid are drawn off and the serum, previously warmed to body temperature, is slowly run in by gravity 4,000 to 8,000 U S A. units according to the severity of the case.

The patient must be kept in a darkened room and the utmost quiet maintained. Any shock or noise however slight induces a spasm. Narcotics, in full doses should be freely administered, such as chloral 30 gr potassium bromide, 15 gr., every four hours, until the spasms decrease paralytic may be given in alternation. Morphia may be given in addition to the above.

J. H. SENNA.

Kuemmell Th Result of Prophylactic Vaccination Against Tetanus (Die Erfolge der Schutzimpfung gegen Wundstarrkrampf). Berl. W. Wochenschr. 9 6 14 4

Kuemmell dwells on the conservative course followed by surgeons in the early part of the war and the changes which were instituted owing to the appearance about September 1914, of gas phlegmon and tetanus. Very little success was obtained in the treatment of tetanus and the mortality was very high. Madelung showed a death out of 22 tetanus cases. In different hospitals it ran from 50 to 100 per cent. However, since the wounded have been given prophylactic intramuscular injections of 50 units of antitoxin tetanus has almost disappeared. I quote show that in one hospital out of 483 prophylactically vaccinated cases there was only one death. In one of Kuemmell's field hospitals where there were 372 wounds of a severe nature, due to grenades or shrapnel after antitoxin vaccination no case of tetanus developed.

Out of 1,355 very severely wounded cases treated prophylactically, there was only one tetanus case which was fatal. From inquiries among his colleagues Kuemmell finds that only 42 cases of tetanus were known to have developed during the past ten to eleven months although the conditions were the same as before except for the prophylactic treatment. Of these 42 cases 9 had not received prophylactic vaccine. Among 8 French prisoners whom Kuemmell vaccinated from six to eight days after they were wounded, there were 4 deaths from tetanus.

In good many of the cases that have been reported where tetanus appeared after the administration of antitoxin, the antitoxin was given very late. Protection can only be counted on for fifteen days, and if the infection is severe for more than a week. The first protective vaccination must be repeated within seven days if surgical intervention of any kind is made or is to be made. If there are further interventions it is well to repeat the precautionary injection. Kuemmell thinks that the relatively small number of failures after protective

inoculation will be reduced with the perfecting of the serum inoculation technique and avoidance of errors in its administration as well as the early treatment of all suspected cases.

There is only a comparatively small number of individuals who are especially susceptible to the tetanus poison, and for whom prophylactic treatment is of little avail. For the treatment of tetanus itself no good results follow any known treatment and thus the practice must be to immunize the body against the working of the tetanus poison.

W. A. BREXMAN

Robertson H. E.: The Present Status of Magnesium Sulphate in the Treatment of Tetanus
Arch. Int. Med. 1916 xvii, 677

Robertson gives a comprehensive review of the clinical reports of the use of magnesium sulphate in the treatment of tetanus. From a careful study of the individual reports it is readily apparent that antitetanic serum not only holds a valuable place in the treatment of all cases of tetanus but also that the administration of magnesium sulphate by intralumbar injection has brought about a definite decrease in the percentage of deaths from tetanus. The same may be said of the subcutaneous method but the intravenous method has been disappointing.

The deleterious effects of magnesium sulphate is an important factor in its administration. An overdose may result in sudden death from its effect on the heart or its centers in the spinal cord. This accident has not followed the subcutaneous method and as death takes place instantly there is no treatment. The most frequent bad effect is from depression of the respiratory center, this can be combated by the administration of calcium chloride 50 cc. of a 2 per cent solution into the muscles. Physiological salt solution would rapidly give relief or the administration of 1 mg. of physostigmin or eserin. The good effects of these drugs are not so apparent when the magnesium sulphate has been given by an intralumbar injection, and it was suggested to wash out the subarachnoid space with normal salt solution.

He quoted Meltzer as suggesting the following dosage. Intraspinal, 1 cc. of a 25 per cent solution for every 22 pounds of body weight. Subcutaneous 12 cc. of 25 per cent solution per kilo. As the subcutaneous injection is painful it may be necessary to precede the injection by some local anesthetic as novocaine.

D. L. DESPARD

Emery W. D.: Some Factors in the Pathology of Gas Gangrene
Lancet Lond 1916 cxc, 948.

Gas gangrene is described as the most interesting disease of the present time. It is of equal interest to the surgeon and pathologist. To the latter it is of special interest because it is a disease caused by an organism most virulent under certain conditions and absolutely non pathogenic under others.

The disease may appear in a slight wound and the part may become gangrenous in as short a space

of time as two hours when it emits a peculiar disgusting odor. This odor may be thrown out by the body of the wounded and the nurses have become so sensitive to its presence that they recognize it as the death smell. Death may take place with profound toxic symptoms in thirty hours. It is apt to develop much later at the base or after arrival in the home hospital. The amount of gas varies. The worst cases show but little or no gas in the tissues. In others there is much gas under tension so that the tissues crackle on palpation. The lesion may be local with sloughing when there is no toxæmia present.

The symptoms of gas gangrene are induced by a bacillus which is almost devoid of pathogenic powers first described by Welch as the bacillus aerogenes capsulatus it is more commonly called in England the bacillus perfringens. Though an anaerobe it is not strictly so. It grows in milk the cream at the top acting as a seal to prevent access of oxygen. It forms spores on media which contain proteids by preference. When grown on media containing glucose it forms enormous quantities of gas without depositing spores. The bacillus is but slightly pathogenic for rabbits a trifle more so for guinea pigs and is equally non pathogenic for man in whom it is a normal inhabitant of the alimentary canal causing no harm. Furthermore it is present at a certain stage in almost all wounds giving rise to no special pathogenic effects and this is especially true when the organism is present alone and unmixed with streptococcus or staphylococcus infections. Cases of hæmorrhax and wounds of the knee have been known to recover where the organisms were found in vast numbers and where there was no rise in temperature. Such contradictions have caused observers to wonder if the Welch bacillus is actually the cause of gas gangrene. All evidence points to the origin of gas gangrene from this bacillus however. The bacillus of malignant œdema is at times associated with it but its presence is difficult to detect. The mixed infections studied are not specially concerned in the development of gas gangrene.

Why is it that gas gangrene fails to develop in all the wounds in which its presence has been demonstrated? (1) We know that the bacillus is killed by the blood serum and plasma. (2) The toxin of the bacillus will inhibit emigration and kill leucocytes when present in large amount. (3) In cases of gangrene millions and millions of bacilli are found but very few leucocytes. (4) Dead and lacerated tissues, thoroughly inoculated with dirt and a large blood-clot are usually found in the worst of the war wounds such as shell wounds. In such wounds bacterial growth will take place unrestrained and if there is no free escape of the toxin it will accumulate to such an extent that when it soaks through into the healthy tissues the leucocytes are killed on the spot growth continues and spreading gangrene is set up. This condition is facilitated by interference with the blood supply. This may

explain the reason for the frequent appearance of gas gangrene in the forearm and leg in which the muscles are enclosed in fibrous aponeuroses in which they are rapidly strangled if swelling takes place therein. (5) Another point to be mentioned is the fact that the toxin, when it reaches vein causes thrombosis, and the vascular supply is still further interfered with. (6) The mere presence of devitalized tissue is not sufficient to give rise to the alarming symptoms of gas gangrene but its presence in the absence of drainage offers a bad prognosis.

As to treatment early drainage removal of clot and dead tissue encouragement of the circulation re-establishment of tissue surfaces to health by the use of hypochlorous solution, and promotion of lymph lavage by hypertonic solutions, are the best methods of treating wounds with gas gangrene or those that are threatened with this virulent infection.

LOUIS A. LAQUER.

Ritter. Gas Burns (Ueber Gasbrand). *Beitr. Hl. Chir.* 9 5, 1911, 47.

Ritter gives his experience regarding the frequent wound infections due to the gas bacillus and which he terms gas burns. The disease is characterized by the formation of gas and by the burning up of the tissues. It should not be termed gas phlegmon (connective-tissue inflammation). Inflammation and suppuration usually accompany the injury but are not a necessary part of the clinical picture. The disease is caused by an anaerobic gas-forming bacillus. Ritter thinks it necessary to emphasize the liability to direct infection from the disintegrated matter of dead bodies lying near the trenches.

Gas burns may be noticed very soon after the onset of an injury. The author has found it twelve hours afterward. There are two forms the epifascial type which develops usually without danger and the subfascial which is always serious. Death may result but this is due not to sepsis, but to blood infection caused by invasion of the bacillus.

The infection may be strictly local and many of the worst cases are of this type. Such local infections are characterized by an abnormally high number of thromboses in the beginning of the process. Although such local infections are most frequently situated in the extremities, Ritter has found them in the brain, lungs, etc.

In 1,900 injuries he observed 43 cases of gas burn 2 were in the lower extremities 6 in the upper 7 in the breast, neck, and abdomen 4 in the brain 4 in the lung.

Ritter figures his mortality in these cases as 43.9 per cent. According to Kuenmell about one third of gas burn cases are fatal. Ludeck had a mortality of 85 per cent and Franks 53.4 per cent. When death occurs it is usually on the second or third day after the first symptoms are noted.

The treatment varies. In light external cases broad incisions usually give good results. Even in cases of deep-seated injuries repeated incisions with

chemical agents will mostly effect a cure, but the incisions, etc. must be thorough, and all pockets necrotic areas, etc. must be thoroughly opened up and excised.

Of 5 cases thus treated by Ritter he lost only one.

As a prophylactic the author recommends Bier's passive treatment.

If thinks the best results are obtainable from combining free incisions with the Aetix method. His procedure is to widely open up the orifice of the wound and clean away all debris so that nothing but fresh tissue is left. The trajectory of the bullets, etc. are also opened up as far as possible. All openings are thoroughly washed with soap and hot water.

The soap is rubbed in to the tissues and rinsed away with water. By this treatment the author had success in some advanced cases which did not present themselves for twenty-four to thirty hours after injury. He emphasizes the necessity for radical excisions in such cases.

W. A. BREWSTER.

SURGICAL ANATOMY

Roux, P. and Jones, F. S. The Protection of Pathogenic Micro-Organisms by Living Tissue-Cells. *J. Exp. Med.* 9 6, 1911, 601.

The authors point out that there are a number of important diseases among them leprosy tuberculosis, gonorrhea, Leishmania, caused by microbe parasites which live more or less habitually within tissue cells. The part played by the host cells in the life of such micro-organisms and also in the distribution within the body of the diseases they induce has obvious importance. They found that it was impossible to make direct *in vitro* tests with the micro-organisms mentioned and the cells in which they live for the reason that they fail to give rise to circulating antibodies active enough to be suitable for the tests. But the problem can be approached, they found, by means of artificial systems, for example by submitting leucocytes that have ingested bacteria to a bactericidal serum and observing its effect on the intracellular organisms.

Their experiments had led to the discovery of a protection against a foreign antiserum, protection against an inorganic disinfectant and homologous antiserum and from their work a number of facts seems proven.

Living phagocytes are able to protect ingested organisms from the action of destructive substances in the surrounding fluid, and even from strong homologous antiserum.

1. There is evidence that the protection by phagocytes is largely if not entirely conditioned on their being alive.

2. These facts should be taken into consideration in the study of diseases caused by infectious agents capable of living within tissue-cells.

But they finally point out that it remains to be determined how far the protection of micro-organisms by living tissue-cells, especially cells incapable

of killing the micro-organisms is important in disease processes. The phenomenon may have much to do with the survival in the animal body of organisms such as the leprosy bacillus which is so often found living within cells of the fixed tissues and it may serve to explain in part the therapeutic difficulties in such instances. It may throw light further more, on the formation of new disease foci at points of injury in individuals of high general resistance. For if an infective agent can be walled off from the action of the body fluids by the protoplasm of a single cell containing it there is no reason why it should not be carried unharmed wherever this cell goes.

GEORGE E. BRILLAY

Robertson, T. B., and Burnett T. G. The Influence of Tethelin and of Other Alcohol Soluble Extractives from the Anterior Lobe of the Pituitary Body upon the Growth of Carcinomata in Rats. *J Exp Med* 1916 xliii 63.

One of the authors recently succeeded in isolating the growth-controlling principle, tethelin, from the anterior lobe of the pituitary body. The methods of isolating the substance its chemical properties and physiological actions and the evidences of its identity with the growth-controlling principle have already been published. It has also been already pointed out that the hypodermic administration of emulsified tissue of the anterior lobe of the pituitary body to rats either directly into or in localities remote from the tumors, leads to a remarkable acceleration of the growth of the Flexner-Jobling carcinoma, especially during the period of growth between the twentieth and thirty seventh days succeeding inoculation. This effect is specific since similar administrations of liver tissue during the same period far from causing any acceleration of the growth of the tumors actually resulted in a slight but definite retardation of their growth.

In view of these results it appeared of importance to ascertain whether tethelin also reproduces the effect of the whole anterior lobe upon the growth of carcinomata, and to that end the investigations which are about to be described were undertaken. At the same time it seemed advisable to the authors to ascertain whether any other alcohol-soluble extractive of the anterior lobe of the pituitary body exerts any action upon the growth of carcinomata. Three such fractions were prepared and their action upon the growth of carcinomata was investigated, with the following results:

1. The hypodermic administration of tethelin increases markedly the rate of growth of the primary tumor and the tendency to form metastases in rats inoculated with carcinoma in this as in other respects, reproducing the action of the whole anterior lobe of the pituitary body.

2. Other alcohol-soluble extractives of the anterior lobe of the pituitary body with the exception of the lecithin fraction, exert no appreciable effect upon the growth of carcinomata in rats.

3. The lecithin fraction as in previously reported

experiments in which the authors employed lecithin obtained from eggs causes evident retardation of the growth of carcinomata in rats.

GEORGE E. BRILLAY

Higgins H. L. Peabody F. W. and Fitz, R. A. Study of Acidosis in Three Normal Subjects with Incidental Observations on the Action of Alcohol as an Antiketogenic Agent. *J Med Res* 1916 xvi 3.

The authors call attention to the fact that it has long been known that the administration of a carbohydrate free diet causes the development of a moderate acidosis in normal persons. The experiments in this paper were designed to obtain further data primarily on the production of acidosis induced by a carbohydrate free diet and its effect on the metabolism of normal individuals and incidentally on the action of alcohol on such an acidosis. The subjects made use of were three healthy men between the ages of 25 and 33 years. The diet which consisted chiefly of eggs, butter, meat, fish and sugar free cream was practically carbohydrate free. It was prepared with great care in the diet kitchen of the Peter Bent Brigham Hospital, under careful supervision and was served in an appetizing manner. The subjects endeavored to eat about 3500 calories per day, largely of fats with the idea of getting a high degree of acidosis but they did not relish so much food and on some days could not take it all. The general plan was to make observations on the gaseous metabolism and urine on one day when the men took an ordinary mixed diet then on three days with carbohydrate free diet then on one day with carbohydrate free diet plus whiskey and finally on a sixth day a diet with the same protein and caloric content but with much of the fat replaced by carbohydrate.

Total nitrogen in the urine was determined by the Kjeldahl method. Urinary acidity and ammonia were tested by Folin's methods. The hydrogen ion concentration of the urine was determined by the method of Henderson and Palmer. Acetone was distilled by a method suggested by Scott Wilson and titrated by the Messenger method. β -oxybutyric acid was estimated by the Shafer and Marriott method. Bang's micromethod for blood sugar was used and Marshall's urease method for blood urea. The alveolar air was taken by the method of Haldane and Priestley with a Siebeck valve. Four samples two at the end of expiration, and two at the end of inspiration were taken before and after the morning and afternoon metabolism experiments and just before the subjects went to bed at night. The gaseous metabolism was determined by means of the Tissot spirometer and the Haldane gas analysis apparatus.

In three healthy subjects a carbohydrate free diet caused the development of varying degrees of acidosis. The acidosis was shown by a lowered CO_2 tension of the alveolar air by an increased urinary excretion of ammonia nitrogen and of

acetone bodies, and by the increased titrable acidity of the urine. The acidosis was accompanied by subjective sensations of malaise, an increased oxygen consumption a negative nitrogen balance increased pulse-rate and increased ventilation. Alcohol given to the subjects on this diet in dosage comparable to that used for clinical purposes did not stop the progress of the acidosis or show any antiketogenic action. Coincidental with its administration there was further increase in the oxygen consumption and in the disagreeable subjective symptoms.

GEORGE E. BEERY

Pellegrini E. Intestinal Function in Pancreopathic Conditions (Fondazione testuale pancreopatica) *Chir. med. ital.* Milano, 9, 5, li 65

The pancreatic function must be studied in two ways according to the fluids which pass from the gland into the intestine and according to the wider and more general action which the products of intestinal secretion exercise on the organism.

The author states that a thorough investigation of pancreas functioning has been carried out in Magrignano's clinic in the University of Genoa. The results from various standpoints will be published from time to time. The methods of research are described in great detail as well as the clinical histories of ten patients and some controls, the results being elaborately tabulated.

From the results the author draws these conclusions:

1. In determinate pancreatic lesions the coprologic tableau is constituted as follows: (a) stools rich in water with abundant alimentary residues excessively steatorrheic with desquamatory elements (b) stools deprived almost wholly of sterco bilin with a reaction principally alkaline (c) stools rich in unmodified albuminoid residues (d) stools with augmentation of undigested carbohydrates, (e) the formula of fatty matters almost universally inverted the quantity of neutral fatty matters prevails considerably (f) digestion of the nucleus of ingested meat completely suppressed.

2. The coprologic picture shows that in pancreatic disease elimination of water is profoundly modified proteolytic, amylolytic, and especially steatorrheic powers are greatly diminished the nucleolytic power is lowered the external functions of the pancreas are totally compromised.

3. Reciprocally it is certain that the index of the lesions or the insufficiency of the pancreas must be sought in the diminution of the digestive power especially for fats, and in the diminution of the nucleolysis of ingested meats.

W. A. BRENNAN

Auer J., and Maltzer S. J. The Intravenous Injection of Magnesium Sulphate for Anesthesia in Animals. *J. Exp. Med.* 19 6 xiii, 64

The effect on animals of intravenous injections of magnesium sulphate was investigated by the authors about ten years ago and its use in this way in

general was discouraged. However a series of experiments made by the authors with intravenous injection of magnesium sulphate in cases of experimental tetanus, and the meager but satisfactory experience which Kohn and Straub had with the employment of this method in cases of tetanus in human beings, induced the authors to take up the experimental study in animals of the employment of magnesium sulphate by intravenous injection for the purpose of producing anesthesia. This was done as a preliminary test for the desirability of studying the exclusive use of intravenous injections of magnesium sulphate as a means of producing or at least inducing anesthesia in human beings. Their experiments seem to justify the following general conclusions:

1. By the intravenous injection of 4,1,000 magnesium sulphate into dogs at a certain rate a stage can be reached where the abdominal walls are completely relaxed and when section of the abdomen and stimulation of sensitive parts of the peritoneal peritoneum do not produce pain or elicit any reaction of the animal. At the same time spontaneous respiration may still be maintained within normal limits and the lid reflex be fair or even normal. In this state intratracheal intubation for artificial respiration can be easily accomplished. This stage may be attained in twelve to fourteen minutes when the rate of injection is about 3 ccm per minute. When this stage is attained the rate of injection should gradually be reduced otherwise sooner or later spontaneous respiration will be abolished and by a further maintenance of the rate of injection all the skeletal muscles may become paralyzed.

2. When the injection of magnesium is continued for a longer period, the paralytic effects of the magnesium injection will set in even when administered at a slow rate.

3. The paralysis of the respiratory function is readily met by intrapharyngeal insufflation which is easily executed even without training in this procedure or by the method of intratracheal insufflation, if executed by one trained in its management.

4. When the respiration of the animal is accomplished by insufflation, the paralytic effect of the magnesium may be abolished fairly rapidly by an intravenous injection of about 5 ccm of an 8,1,000 calcium chloride solution or it may disappear slowly after the infusion of the magnesium solution is discontinued for some time. The latter mode of disappearance may be favorably accelerated by an intravenous infusion of 60 to 100 ccm. of a 4,1,000 solution of sodium sulphate.

5. The production of anesthesia by intravenous injection of magnesium sulphate should not be undertaken unless an apparatus for intrapharyngeal insufflation is at hand because in exceptional cases the disappearance of spontaneous respiration may be one of the earliest consequences of the magnesium injection.

6 The injection of calcium chloride should not be employed in cases in which the subject shows cardiac insufficiency. In such instances moreover injections of magnesium should not be used for the purpose of anesthesia at least not until greater experience has been acquired in the employment of this method.

GEORGE E. BEILBY

Pellegrini E. Stercobilin (Sulla stercobilina) *Chimica Medica* Milano 916 li. 791

Pellegrini presents some of the results obtained in experimental researches on intestinal function carried out at Maragliano's clinic in the University of Genoa.

The results were obtained from observation of patients in whom there were more or less notable gastro-enteric disturbances. The methods followed for the estimation of urobilin in the urine were those of Mareschal Huppert and Hammarsten and for biliary pigments those of Gmelin and Nencki. Gmelin's method of blood examination was followed.

The results show that there is an agreement in the conditions of elimination between stercobilin and urobilin in conditions in which these pigments are eliminated normally. This normal urofaecal elimination exists in spite of disturbances of the digestive apparatus caused by gastric, enteric, cardiac and other lesions. In hepatic lesions stercobilin diminishes rapidly until only minute traces are left and icterus may or may not be present. In such patients the elimination of urobilin takes the form of pathologic urobilinuria and this is particularly noted in the case of pancreatic subjects.

The facts appear to show that hepatic conditions notably influence the elimination of urobilin and that in cases where stercobilin is absent the elimination of urobilin is pathologic. W. A. BRUNNAN

Gates, F. L. and Meltzer, S. J.: An Experimental Study of the Additive and Antagonistic Actions of Sodium Oxalate and Salts of Magnesium and Calcium in the Rabbit. *J. Exp. Med.* 1910 xlii 655

On the basis of the hypothesis that magnesium favors inhibition of the various functions of the nervous system, Meltzer and Auer studied extensively the action of magnesium salts upon various animals. In injecting magnesium sulphate subcutaneously they found that a certain dose which varies with the species of animals is capable of producing profound anesthesia and paralysis from which the animal recovers. For rabbits this dose amounts to about 1.5 gm of magnesium sulphate ($MgSO_4$ and 7 H_2O) administered in a molecular solution. Larger doses cause the death of the animal as a rule by respiratory paralysis. With an effective but non-fatal dose in subcutaneous injections the development of the depressing inhibitory effect is gradual and fairly slow.

In the course of their studies Meltzer and Auer found that calcium which is chemically closely

related to magnesium is biologically apparently the antagonist of the latter. When calcium is injected intravenously shortly before or immediately after the respiration stops into an animal which has received a fatal dose of magnesium the animal will recover in less than a minute provided of course that the circulation is still effective during the calcium injection.

The problem which the authors have endeavored to solve experimentally in this study is: Can the depressing component of the calcium precipitating oxalate be brought out by a simultaneous administration of a subminimal dose of a magnesium salt? Their experimental study seems to have firmly established the following facts:

1 Subcutaneous or intramuscular injections of sodium oxalate in subtoxic doses when administered to an animal which has received a subminimal dose of magnesium sulphate produce profound anesthesia and paralysis of long duration although the usual effects of sodium oxalate alone are of a stimulating character. This fact is in general in harmony with the results reported by Starkenstein who however seems to have used the combination of the two salts in one solution namely that of magnesium oxalate.

2 The combined injections of subminimal doses of sodium oxalate and magnesium sulphate produce a strong reduction or even at times a complete abolition of the conductivity of the motor nerve endings.

3 An intravenous injection of calcium salts brings on a recovery from the profound and prolonged effects of the combined action of sodium oxalate and magnesium sulphate which is as prompt action as is observed in experiments in which effective doses of magnesium alone are given. This fact is the more noteworthy since depressions of long duration produced by prolonged continuous injections of magnesium solutions alone do not respond very promptly and effectively to calcium injections.

As will be recalled the starting point for this investigation was the hypothesis that substances which are capable of precipitating calcium—a biological antagonist of magnesium—ought to be capable of increasing the depressive effect of magnesium. The authors' experiments proved that this assumption was correct. This would seem therefore to justify the interpretation that the augmenting action of sodium oxalate has its cause in the ability of the latter to precipitate calcium and thus increase within the body the amount of unantagonized magnesium. However they state expressly that this view is for the present still no more than a hypothesis and does not exclude other possible interpretations of the facts. As they pointed out it speaks against this hypothesis that oxalates do not produce phenomena of depression the toxic symptoms produced by oxalates exhibit distinct signs of increased and not of decreased irritability.

GEORGE E. BEILBY

Lewis, D. The Appearance of the Precursor Substance in the Fetal Hypophysis. *J. Exp. Med.*, 19 6, xiii, 677

It has been demonstrated that the precursor substance of the posterior lobe of the hypophysis is secreted by the pars intermedia, a derivative of the pharyngeal pouch. The present study was undertaken by Lewis with the hope of determining at what period in fetal life the precursor substance appears and of correlating the cytological changes in the pars intermedia with the establishment of secretory function using the appearance of the precursor substance as an index. He found that the hypophyses of pigs just before birth were large enough to permit of separation of the two lobes, but in the earlier stages this was impossible. In order to secure uniform material for injection the extracts were made from the entire gland in all instances. The glands were obtained fresh and extracted in absolute alcohol to remove the depressor substances. After extraction was completed the alcohol was filtered off and the residue dried in a desiccator. The dried residue was kept in small bottles until desired for use when a salt solution extract was made for intravenous injection.

As a result of his experiments Lewis concludes that the precursor substance of the hypophysis is so marked in the pig fetus measuring 175 mm. that it seems probable that a fetus of this length is independent of the secretion of the mother's hypophysis.

GROSV. E. BISSON

Alberti, O. Tubercular Bacillæmia—A Clinical-Experimental Study (*Staph. bacillus tubercularis*). *Clin. anal. Biol. Milano*, 9 6 II 15

A question which has occasioned a great deal of discussion in recent years is that which refers to the presence of the Koch bacillus in the circulating blood of individuals attacked by tuberculosis. The author reviews the voluminous literature commencing with Willemin's animal experiments in 1868 down to the present time. In his opinion the discord which exists in the findings of the different authors is to be explained by faulty methods in the technique employed.

He, therefore, undertook to carry out a series of experiments following a rigorous technique designed to exclude possible sources of error. He examined the blood of 50 individuals, of which 30 were unquestionably tuberculous, 10 were suspected and 10 were clinically healthy. In 35 cases the complete research was made double microscopic examination by the methods of Staubli-Schnitter and Rosenberger; and parallel with this a biologic test comprising inoculation of the blood in the peritoneum of guinea pigs.

In the other 15 cases the research was limited to the biologic test alone. Bacterioscopic examination in the 35 cases gave 5 positive results with the Staubli-Schnitter method and 3 with the Rosenberger method.

Biologic tests in the 50 cases and with 78 guinea pigs have given 11 manifestly positive results. Commenting on these results the author thinks that tubercular bacillæmia is met with very infrequently and is only manifested in tuberculous individuals it is an inconstant and transitory phenomenon which ought not to be considered—at least as far as chronic tuberculosis is concerned as a true septicæmia, but simply as a bacteræmia of little clinical importance. Tubercular bacillæmia has no relation to the degree of gravity of tuberculous lesions and has no practical value from either the point of view of diagnosis or prognosis. W. A. BROWN

Descomps, P. Epiploon and Pericolicitis (Epiploon et pericolicite). *Rev. d. chir.*, 19 6, xxv, 109.

For some years past many articles have been written on the rôle of pericolicitis in the pathogenesis of chronic colitis and stasis. Inflammations and stasis in the colon usually localise in certain so-called "hot spots," the terminal ileum and initial segment of colon, the transverse colon, and colonic angles.

In this large territory there is a special segment in which inflammation and stasis occur in the majority of cases. This is the right colonic segment. The anatomico-physiological conditions found there are of capital importance and show the part played by the epiploon and therefore by epiploitis in the production of pericolicitis and consequently of colitis and stasis in this segment.

The author therefore devotes the greater part of his article to a study of the anatomy of the epiploon including the arteries, veins, and lymphatics.

Walther and his pupils have at various times from 1868 to the present shown the connection of epiploitis and chronic colitis, and Descomps himself basing his remarks on 36 observations of Walther has shown the preponderant part played by the epiploon in the pathogenesis of pericolicitic phenomena and the favorable effects produced by epiploic resection and liberation of pericoliconic adhesions as a complement to appendectomy.

There are two ways in which the epiploon may be involved. First, by the formation of adhesions with the neighboring organs and especially with the right colon. Such adhesions may be primitive, i.e. anatomic in type, or they may be pathologic, inflammatory adhesions. Of this latter type are the restricting bands, derived from the epiploon, which give rise to the so-called membranous pericolicitis. The second way in which the epiploon may be involved is less known but not less important. It may become inflamed and sclerotic without forming pericoliconic adhesions. The loss of suppleness and mobility of the epiploon gives rise to pericolicitis and stasis. This type is frequent and in the most recent statistics of Walther this non-adherent type was found 19 times as against 8 of the adherent type.

W. A. BROWN.

RADIOLOGY

Boggs, R. H.: The Treatment of Epithelioma of the Lower Lip. *Internat Jt J* 1916 XXII, 114.

Epithelioma of the lower lip however innocent in appearance is nevertheless cancer and often shows a degree of malignancy that is not usual in epithelioma in other situations. It seems to be rather a regional than a local lesion. The lymphatics which drain it should in every case receive the same attention as the visible lesion. Until recently the best routine treatment has been early surgical removal of the ulcer and lymphatics. Today the general practitioners commonly refer lower lip epithelioma to a radium therapist because they can be successfully treated by this method.

At first pioneer work had to be done and the disappointments were many. Radium was scarce the apparatus elementary and the limitations many and serious. Only cases of which surgery despaired built their last hope on radiotherapy. The results were necessarily uncertain and a severe test of the new medical faith and hope. Yet there were excellent results that justified the hope of the physician and the confidence of the patients. In consequence with our present supply of radium the powerful transformer and the Coolidge tube we now stand on firm scientific ground and radiotherapy has a definite place in the treatment of malignancy. To-day the radiotherapist has a broad and on winning clinical knowledge of his subject. The author is convinced that at present radiotherapy is the best routine treatment for epithelioma at any stage and he also believes that this will be the ultimate decision of every modern physician. He wishes however to caution against haggling radiotherapy of lip cancers as much as against haggling surgery of them. Radiotherapy to be reasonably successful, demands competent application. Radiotherapeutic treatment of lower lip epithelioma was discussed at a recent meeting of the American Dermatological Society and it was agreed that it is a legitimate and successful treatment in properly qualified hands. That epithelioma can be eradicated by radiotherapy has been definitely proved and in advanced cases it offers more hope than any other method. Cures have been effected in far advanced cases but the sooner a precancerous change is treated the better prophylaxis always being the safest and the surest. It is only fair and just however that at present no one should attempt this treatment without adequate previous training and experience under proper direction.

The technique must in every case be adapted to the individual patient and his needs. Scientific dosage is a matter of physics and of therapeutics. Physical dosage can be measured exactly but therapeutic dosage depends on the technical and practical judgment of the physician. As an instance in point the author prefers radium used locally for epithelioma of the lower lip and for the adjacent glands radiation with the Coolidge tube. One

capsule is placed inside another on the lip and another on the outside of the lip to secure complete irradiation. Usually the first reaction is sufficient for healing a moderate lesion but the scar must be healthy pliable without retraction and without ulcers before a case can be considered clinically cured. The treatment of the adjacent glands must never be neglected even for the small lesion. Any partial removal of an epithelioma must be condemned.

The author's conclusions are as follows:

1. Every cancerous epithelioma of the lower lip is to be treated because experience has shown that this epithelioma is a regional rather than a local lesion.

All precancerous lesions should be treated by a method that leaves no scar whatever.

3. Many hold the result of radiotherapy to be as good and even better than that obtained by surgery and that surgery should be resorted to only in selected cases.

4. There are a number of radiotherapists who have had sufficient experience with epithelioma of the lower lip and who have obtained results that justify them in considering radiotherapy a perfectly legitimate method of treatment.

5. Inefficient work as it is being done by those who have simply bought the usual apparatus and received some instructions in its use from the manufacturers cannot be too emphatically condemned nor too strongly deprecated.

Boggs, R. H.: The Treatment of Tuberculous Adenitis by Roentgen Rays. *Int Jt J* 1916 XXII, 106.

As the end results in cases of tuberculous adenitis treated by the roentgen rays are generally satisfactory, Boggs believes many cases that are subjected to surgical procedure could be better treated by radiation thus sparing the unsightly scarring with the not infrequent sinuses which when long delayed in healing are often finally referred to the radiologist. As is well known operation is often followed by local recurrence and at times gives rise to a general tuberculosis of the diseased glands often being of wider distribution than the clinical signs indicate making it difficult and at times impossible to remove them. The contrast is marked and it is alleged 90 per cent of these cases are permanently cured by radiation, it would seem that this method should be adopted as a routine. Radiation in these cases should not be confused with that employed in the treatment of malignancy, and while hard rays are to be used they should not be given in massive doses as the general system must dispose of the products of degeneration and it is better not to overload it, especially when as a rule it is greatly impaired.

Since the rays are not bactericidal the beneficial effect must be produced by destroying tissue of low resistance thus rendering the soil barren but attention is called to the fact that Crane has advanced the theory that by this process an autogenous

vaccin is set free and this is given in explanation of those instances where a tuberculous process at some distant point from that treated will likewise disappear. The observation has also been made in cases where tubercle bacilli have been found in the sputum, subsequent examinations failed to show their presence. While treating these cases, especially those about the neck, careful inspection must be made for local sources of infection in the mouth and throat, bad teeth, and swollen tonsils but it is by no means necessary to remove every swollen tonsil for many will improve after the glands subside. When a chain of lymphatic glands has been properly rayed the glands and vessels undergo a fibrous degeneration with almost entire obliteration, with no marked influence upon the surrounding tissues. Attention is called to a series of 344 cases collected by von Mutschersacker where operation was found necessary in only 9 per cent. Mathews is also quoted and his view some against operation is given. Boggs has also considered the possibility of mistaken diagnosis but calls attention to the fact that such conditions as Hodgkins disease and sarcoma also call for radiotherapy.

W. S. NEWCOMB

Gerber I. The Use of the Polygram in Gastro-duodenal Diagnosis. *Am J Roentgenol* 9 6 13, 20.

Gerber for the past several months, has been using the polygram method of Levy Dorn modified somewhat by the use of modern instrument and technique and has found it almost indispensable in gastroduodenal examinations. He makes only two exposures on a single plate, with an interval between exposures of about eight seconds. This may be lengthened somewhat in cases with very sluggish peristalsis or hastened but when the peristalsis is extremely lively. The polygrams are made in both the erect and the prone positions.

In the normal stomach, the passage of the peristaltic waves can be seen in a most graphic manner. The two outlines cross and recross each other in such a way as to show clearly that every portion of the muscular wall is taking part in the peristaltic conduction. Thus it can be seen whether or not there is any *Beery's gulf* or regional lack of motility. In chronic gastric ulcer the area of induration will show definitely as portion of the gastric wall that does not take part in the peristaltic conduction. Craters or niches stand out prominently. Incrusts will show as a permanent in cutting easily distinguished from the criss-crossing peristaltic waves. In duodenal ulcer the characteristic deformity is sharply shown. In gastric carcinoma, both filling defects and defects of motility can be observed by this method. In noting pressure from extragastric tumors, distended gall-bladder etc., the polygram may be of considerable assist.

It might be objected that all the above information can be noted on the fluorescent screen. This

is certainly true in some cases, but in many others such as early carcinomas, small antral ulcers and some types of duodenal ulcers, the information is either very difficult or absolutely impossible to obtain from a fluoroscopic study only. Besides the polygram affords a permanent record. In other words, it offers the advantages of serial plates without the great inconvenience and expense of obtaining a large and complete series.

The author does not by any means offer the polygram as a substitute for a thorough serial study but he does believe that it will in many cases save considerable time trouble and expense for those who confine themselves chiefly to the roentgenographic method in the study of gastroduodenal disease.

W. A. E. ANDERSON

Newcomb W. S. The Comparative Value of Roentgen and Radium Radiation in Therapeutics. *Am J Roentgenol* 9 6 13, 203

Aside from the fact that roentgenotherapy has been brought to a high degree of refinement in comparison with radiumtherapy there are cases which appear to fall within the distinct province of each. In superficial epithelioma, the method which gives the best results is merely a matter of technique but in cases of carcinoma in the cavities of the body radium is without a peer.

Upon purely clinical grounds, all things being equal, the treatment of all cases may be divided into two classes.

Those in which a localized radiation is desired and in which these radio-active elements are to be preferred.

Those calling for diffused radiation over a more or less extended area in which roentgen radiation is to be preferred.

Modification must be made in both depending upon the depth of radiation desired.

It has been previously stated that the difficulty of comparing these two forms of radiation is due to the wide variation in technique but generally speaking, the results are obtained from radium with less damage to surrounding tissues than similar conditions treated with roentgen radiation.

The idea seems prevalent that enormous quantities of radio-active element are necessary to produce results. While large quantities are desirable the fact remains that a small quantity judiciously applied will often prove of greater benefit.

In conclusion it might be fairly stated that an exact comparison of the two forms of radiation is extremely difficult due to the wide difference in technique and the wide variation of results reported by various writers in both fields. This is further confused by the fact that many individuals employing these radio-active elements have had very little experience in general radiology. From the author's personal experience and observation, however, it still appears that there is and will be a field for both forms of radiation as well as a very broad common ground where both will yield results equally de-

pending entirely upon the individual technique employed.

W A EVANS

Stewart W H: Roentgen Diagnosis of Obacure Lesions of the Gastro-Intestinal Tract. *Am J Roentgenol* 1916 33: 202

The tendency of roentgenologists of today to ignore the clinical picture and depend almost entirely on the fluoroscopic and roentgenographic findings in arriving at a diagnosis has prompted the author to make a plea for the more general use of every means available in every case combining the roentgen interpretations with the symptoms and laboratory reports before an attempt at diagnosis is made. Too often what apparently was a clear case roentgenologically has been proved to be otherwise when compared with surgical or post mortem findings.

In order that it may be possible to render valuable aid in the diagnosis of gastro-intestinal lesions especially the large number of borderline cases in which the patients suffer from pain and distress in the right upper quadrant and which may be caused by kidney gall bladder duodenal or appendicular disease it is necessary that every effort should be made to educate the medical profession to refer their cases to the roentgenologist for diagnosis and not to restrict his investigations to any one part of the gastro-intestinal tract. Just as a stone in the left kidney may give rise to symptoms on the right side so may the cause of symptoms in the stomach be found in the appendix or in the lower colon. Therefore a negative diagnosis cannot be accepted as final until the entire gastro-intestinal tract has been examined.

Stewart presents a series of cases illustrating the cardinal points which he has attempted to bring out namely that a thorough physical examination and complete history together with a record of the laboratory reports be combined with the roentgen findings of a complete examination before arriving at final conclusions. This series consists of several interesting reports of cases accompanied by illustrative roentgenograms which show conclusively how the roentgenologist had been in full possession of the clinical and laboratory findings in the case would have gravely erred in his diagnosis.

W A EVANS

Holding A. F.: Roentgen Deep Therapy in Malignant Tumors. *Am J Roentgenol* 9: 63, 9

The author's report covers cases which have been observed during a period of three years including not only malignant tumors but also non malignant diseases such as lupus vulgaris keloid acne vulgaris exophthalmic goiter myoma etc. In all cases of non malignant disease, with the exception of myoma exophthalmic goiter and tuberculous adenitis and in cases of superficial malignancy the author urges the use of physical methods rather than surgical for the reason that with physical methods which include roentgenotherapy conglu-

tion and the ultraviolet light a cure is obtained with the best cosmetic result with ut hemorrhage or opening up the lymphatic vessels without pain or the need of an anesthetic and without loss of time from employment or hospital confinement. The results as shown in the tabulations are very convincing.

The author claims priority in the treatment with the roentgen ray of carcinoma testis of teratoid origin and parathyroid gland tumor with very pronounced meliorating effect.

Another group of cases in which improvements have been shown are those of intrathoracic sarcomata and arimomata. Holding urges the employment of roentgen therapy in all of these cases even the most hopeless from all a certain degree of relief can be obtained and some may be even symptomatically cured.

In summing up this series of cases the following conclusions are reached:

1. The most important point in connection with the use of physical methods for therapeutic purposes is that they aid nature to cure superficial malignant tumors much better than surgical methods.

2. Unless roentgen deep therapy it is a common occurrence to have tumors undergo retrograde metamorphosis or even to disappear.

3. In hopeless cases these physical methods enable nature to effect marked amelioration of the symptom.

4. Occasionally this amelioration of symptoms amounts to a symptomatic cure.

5. The amelioration of symptoms is distinctly worth while.

6. If these physical methods ameliorate the symptom in hopeless cases patients having operable lesions should not be denied the benefits of these physical methods after operation.

7. Two forms of tumor not previously reported in medical literature are markedly ameliorated by roentgen deep therapy namely carcinoma testis of teratoid origin and carotid gland tumor.

8. Every effort should be made to perfect the technique and the use of adjuncts to increase the number of symptomatic cures and make permanent the ameliorations.

MILITARY SURGERY

Hagedorn O: Finding of Position of Retained Bullets (Steckschuesse und ihre Lagebestimmung). *Bil M Chir* 9: 61 u. 546

Retained bullets are most frequently found to be shrapnel and they are almost always found to be encysted probably owing to the inflammation caused by the foreign body aided by the blood accumulated round it giving rise to the formation of a cyst.

The first question arising is whether or not the bullet should be removed. The most important objective disturbances indicative of removal are disturbance of motor function and the signs of

vascular or nerve pressure. In the presence of such dangerous symptoms and serious functional disturbances and when the bullet can be reached without further severe destruction of tissue it should be removed.

For localizing the position of the foreign body two roentgen pictures in different projections are usually sufficient, the intersection of such projections giving the line in which the body lies, but when the bullet lies in the frontal part of the hand, in the shoulder or other positions of very irregular contour this method is unsatisfactory and the apparatus devised by Weise has in such cases given good results in the author's practice. The method is simple and satisfactory in its results. W. A. BRIDGES.

Hall, A. J., Keogh, A. H., Fletcher, E. M. *Surgery in War*. Royal Army Medical Corp. Blakiston, Son & Co. Philadelphia, 1916.

This small octavo volume of 583 pages is a summary of the surgical experiences and conclusions of the present European War by Major Hall and a number of other well-known contributors.

The author states that on the bacteriological side Sir A. E. Wright's work as shown by recent surgical developments has revolutionized the method of treating sepsis. The object of the work is to give members of the profession unacquainted with war surgery an insight into what is being done in military hospitals.

Col. E. M. Fletcher points to the definition of military surgery which is after all but the surgery of gunshot wounds, with the broad interpretation understood in military parlance viz. injuries from bombs, hand grenades, and everything set in motion by an explosive compound, as well as wounds from projectiles emanating from rifled arms, both great and small. The vast difference between civil and military surgery is due to the immense difference in the conditions under which the work is done. On the one hand there are conditions in which the environment dominates the surgeon, and on the other conditions in which the surgeon dominates his surroundings. The civil surgeon operates under conditions approaching an aseptic ideal whereas, the military surgeon's field is seldom aseptic but almost always precarious. The wounded man, though he may be fit physically is often exhausted by the fatigue and privations of campaigning when he is stricken on an infected soil on which he is apt to lie for days before surgical aid can reach him. He is next subjected to the trying influences of long and often improvised transport, during which proper food, good nursing, and favorable climatic conditions are frequently absent. The surgeon's difficulties are most trying. Hospitals have to be improvised in the beginning of the campaign. These are often overcrowded from the sudden accession of wounded, which arrive when least expected. The overcrowding often brings scarcity of food and surgical supplies. To add to the difficulties at hand, the wounds, which are all infected and in a class to

themselves, are of manifold varieties, occurring in all parts of the body and involving every tissue.

The foregoing facts justify the claim that military surgery is a special branch of surgery. Moreover every campaign has conditions peculiar to itself. These are distinguished by the moral psychology of the combatants as related to the intensity of the fighting, the numbers engaged, climatic conditions, the character of the country whether hilly or flat and above all the character of the implements employed in inflicting wounds.

In the present conflict the magnitude of the campaign has brought the virile manhood of all the countries involved to the front and with them the most capable surgeons in the world. In this little volume we find how valuable has been the assistance of the civilian members of the profession to the Director of the Medical Services of the British Army and incidentally to the medical world.

A notable point in the present war is the way in which the bacteriologist has developed his indispensable services to the military surgeon. His value to the physician and the sanitarian in campaigns had been well established but never before has the bond between the bacteriologist and military surgeon been observed. Infection and the wound have linked the two together and to achieve success they must work hand in hand. It was through the rational and indispensable work of Sir Almroth Wright and his collaborators that an effective treatment of gunshot wounds has been worked out. Failure to properly arrest infection in war wounds at the beginning of the campaign demonstrated that our antiseptic methods were at fault, and it required the steady influence of the bacteriologists to direct surgical endeavor along proper lines.

Military surgeons in the United States who treated gunshot wounds in the region of the great plains, under cloudless skies, in pure air on soil that had never been a plow were seldom troubled by the complications of varied infections. Likewise the British surgeons who followed the armies in the Boer War gained experience in infection that served no purpose when compared with that obtained in a campaign fought with a great preponderance of wet days, upon a soil artificially sown with bacteria, largely of the fecal kind. This condition has made the labors of the bacteriologist indispensable to those of the surgeon.

The nature of the weapons has played a very interesting rôle also. To future generations the present conflict will be referred to as the Great War but to the surgeon it will be known as the Pointed Bullet War. Although pointed bullets were used in the Turko-Balkan War and other minor conflicts, the present war is the first in which it has been universally and exclusively used in both machine-guns and the military rifle. There has been seen all the ugly wounding effects which were foretold as the result of experimental work. Compared to the effects of the ogival jacketed bullet of the Krag-Jorgensen type its shattering effects on bone is

better marked. Its tendency to turn an impact makes it more destructive to soft parts in the chest and abdomen. Its high velocity and flat trajectory cause explosive effects at longer ranges and it is more apt to break up. When it disintegrates after striking side on it causes wounds not unlike those caused by dum-dum bullets, a fact which has brought about charges of inhumanity on all sides such as those which have been heard at the beginning of all war ever since the advent of the high-power military rifle. Accusations of inhumanity have been made more especially against the pointed bullet used by the British army, because disintegration of this projectile shows fragments from two separate nuclei—one of lead in the body of the envelope and the other composed of aluminum occupying the point of the envelope. The British Government admitted this bullet some time ago for the reason that being a trifle longer than the other pointed bullets it offers more bearing surface against the rifle barrel and thereby is steadied in flight. It is doubtful if the mere fact of a double nucleus adds to the tendency to disintegrate. Those who have experimented with all types of pointed bullets are well aware of the highly destructive effects which have been brought about by the so-called *spite* bullet first adopted by the Germans. It is doubtful if the pointed bullet of one army is more destructive than that of another.

Another remarkable feature of gunshot wounds in the present war is the large percentage of artillery wounds from shrapnel and high explosive shells and to these might be added the wounds caused by bombs and hand grenades. Wounds from these projectiles are attended with a great deal of contusion, hematoma, lacerated and devitalized tissue. They are prone to extensive suppuration, which in turn makes their treatment difficult and laborious in active campaign.

The statistics of war wounds have been withheld by the censor so that nothing is given with which comparison can be made but assurance is given that results are satisfactory and that improvements in wound treatment are being made very rapidly.

The bacteriology of all wounds may be said to be one of environment and for that reason the bacteriology of war wounds is similar to the bacteriology of the terrain on which the battle is fought. The amount of the infecting dose will depend upon the size and character of the wound and the degree of contamination of the skin and clothing. The operations on the western front are being conducted in farming districts in which the soil is richly manured with the fecal matter of animals and man. The consequence is that the virulent types of microbes which find their habitat in such refuse are very prevalent. Broadly speaking the organisms found in the clothing, skin and wounds of men are of the aerobic or facultative anaerobic kind and also the strict anaerobes. The first include staphylococci, streptococci, bacillus pyocyaneus and the members of the colon group and to the second belong tetanus

bacillus, bacillus of malignant edema, the bacillus aerogenes capsulatus of Welch and the indeterminate series to which gas gangrene is attributed.

The exact rôle played by the colon group has not been determined. The action of staphylococci, streptococci and other pyogenic organisms is well known. In their range in the tissue they contribute indirectly to the greater consequences of the action of certain anaerobes which have been earned in the production of gas gangrene. The aerobes have brought about trigonism on quinine in the present war and the effort to represent this condition have been directed against them more equally. The presence of pus is no longer being compared to the clinical evidences of tetanus, malignant edema or gas gangrene.

The purification of these resistant organisms is the merit of the surgeon. There is to the sterilization of instruments and all material used in the treatment of the wound proper. The spores of malignant edema resist a temperature of 100°C for a half hour. Those of bacillus perfringens require 3 minutes boiling. The spores of tetanus in dry soil and discharge remain virulent for many months and in this condition will become resistant so that autoclaving is really the only effective way of killing them. In addition to their resistance to sterilization the anaerobes elaborate toxins locally which do not enter the blood stream until late. This fact is of value to the surgeon and the radical methods of wound treatment employed in all infected wounds at present are yielding excellent results.

Tetanus bacillus is the most important of the malignant anaerobes. The toxin is produced locally in the wound and is carried along the peripheral nerves to the central nervous system especially to the cells of the medulla and pons, attaching itself first to the anterior cornual cells connected with the motor nerve supply of the wound area so that the first symptom of tetanus is a cramp in the injured limb.

The antitoxin is derived from the serum of horses that have been immunized against the toxin. The neutralizing effects of antitoxin with toxin is a mathematical process, the strength of a given antitoxin being estimated by the amount of it which is required to protect a given weight of animal against a simultaneous injection of a lethal dose of toxin for instance 1 cm. of the Pasteur Institute antitoxin will protect 1,000,000,000 grams of mouse against a lethal dose of tetanus toxin and the therapeutic dose of this preparation is 50 to 100 ccm. The presence of tetanus is first heralded by the characteristic symptoms when it is too late to be effected much with antitoxin. It is much easier to prevent the union of tetanus toxin with nerve-cells than to unlock the combination after it has been made hence the value of a prophylactic dose. One can not go wrong by administering antitoxin at once when the nature of the soil where the wound as incurred is known or the presence of bacteria such as bacillus aerogenes capsulatus or other spore-bearing

bacilli are found in the discharges. These are nearly always in association with bacillus tetanus—the latter is difficult to find in a wound.

If tetanus has developed, the dose may not be fatal, or there may yet be free toxin in the central nervous system which should be counteracted by antitoxin injected in the lumbar sac. A good plan is to give an injection of 0 to 15 ccm. of antitoxin in the lumbar sac and 100 ccm. intravenously in one or two injections as rapidly as possible after the onset of the symptoms. The additional intravenous dose insures a high concentration of antitoxin in the body fluids and a rapid and more intense action on the toxin. The administration of antitoxin must be supplemented by thorough eradication of the infected focus, since it is useless to administer antitoxin if tetanus bacilli are left in the wound.

The bacillus of malignant oedema is at times found in wounds, under suitable conditions. There is intense serous exudation in the muscles and subcutaneous tissues, the mechanical pressure of which, with the rapid development of the bacilli, cause obstruction of the vessels and resulting gangrene. It is possible to prepare an antitoxin against malignant oedema, but it has never been used therapeutically.

Bacillus *erogenes capsulatus* (Welch) or as it is sometimes called, bacillus *perfringens* is frequently found in the wounds of this war in association with the bacillus tetanus. It causes free exudation of serum with abundant gas production. The resulting emphysema spreads rapidly stripping up the cellular tissue and permeating muscles. The mechanical pressure of the distention and gas obstructs the circulation, with resulting gangrene.

While bacillus *erogenes capsulatus* is the chief agent in the causation of gas gangrene examination of wounds will at times reveal other gas-producing microbes. The latter are prone to appear in wounds where death has resulted from profound tetanus. Pure infections of bacillus *erogenes capsulatus* are not fatal as a rule. These additional organisms are of the anaerobic kind, they produce soluble toxins which are powerful depressants to the heart—the feature of the case being loss of consciousness and an imperceptible pulse.

The shattering effects of a shell-wound or the explosive effects of a wound from the military rifle at close range in the thigh for instance, is a good example of the ideal conditions for anaerobic infection. The projectile carries soil contamination covering skin or clothes deeply into the tissues, shattering the bone, the fragments of which act as secondary projectiles, carry infection into pockets in different directions. The hematoma, contusion laceration, and devitalized tissues provide for the growth of bacteria ideal conditions in a number of foci which are closed by prolapsed muscle and other tissues, and thereby rendered inaccessible to the air. The difficulty of removing the bacteria from such a wound and of preventing them from obtaining a foothold and elaborating their toxins must be obvious.

The bacteria can be removed from such a wound only by free drainage with frequent washing with antiseptics. The advantage of the flow of lymph promoted by such agents as hypertonic saline and eusol (hypochlorous acid) has been well demonstrated in this war. The use of eusol is particularly favored since it adds to its lymph lavage properties, that of being acid which is in itself inimical to the production of toxins. It also opposes the absorption of toxins by the flow of lymph which it induces and by relieving the local tissues of exudate it prevents the mechanical pressure on the vascular supply which is a contributing factor in preventing gangrene.

The use of vaccines against anaerobic infection is not attended with success. The patient is quickly overwhelmed by the toxins, long before the vaccines can have any effect. The role of vaccines lies more in building up resistance against pyrogenic organisms, such as staphylococci and streptococci, in cases of long continued suppuration and fever.

The general condition of the wounded is dealt with largely from the standpoint of shock and in this especially the author is partial to the teachings of Crile who believes that shock is a condition of exhaustion and low blood pressure which may be caused by pain, hemorrhage, sepsis, worry and fear. He has shown that painful stimuli can reach the brain even in a state of general anesthesia, causing exhaustion of the brain-cells. In consequence of brain-cell exhaustion, there is derangement of vasomotor mechanism and lowered blood pressure.

To prevent shock he prevents painful stimuli from reaching the brain-cells. Painful stimuli may reach brain-cells during general anesthesia but they may be blocked by means of local anesthesia. Crile has elaborated many methods of anesthetic association, as it is called, all being attempts to guard the brain-cell from exhaustion by blocking the various paths of painful stimuli.

Aside from local anesthesia the administration of morphine before operation is employed. This lowers the receptivity of the nerve-cell. Morphine is a sheet anchor in preventing shock given in 4-gr. doses with 1/50 gr. of scopolamine which may be repeated if the patient shows by training or rapid breathing that painful stimuli are still reaching his brain.

The next measure employed to prevent shock is to maintain the blood-pressure. This may be accomplished by pneumatic contractions not suitable in war. Bandaging of the extremities is beneficial in falling circulation in the presence of shock.

The pressure may be maintained by transfusing blood (Crile) which is better than saline solution, which exudes from the vessels and may accumulate in loose tissues about the abdomen in sufficient quantities to embarrass respiration.

Adrenalin may be added to the solution to be transfused and pituitary extract in appropriate doses has been used. Crile says that atropine stimulates the brain-cells and acts harmfully alcohol is

not much better. Camphor and caffeine are used by some.

At the first aid station the hemorrhage should first be arrested, the gross soiling of the wound removed, first aid dressing applied, morphine given to relieve pain and fixation applied wherever possible. The use of alcohol and strychnia should be avoided but the patient should be given hot tea or caffeine. Fluids should be given to sustain blood pressure.

At the clearing hospital all serious wounds are re-dressed under an anæsthetic. Patient with compound fractures are in-sed to favor free drainage and care should be taken to apply a well fitting splint that will not cause pain. When deemed necessary or advisable it is well to use some form of regional anæsthesia. This may be practised upon those who have been operated on or in severe fractures to avoid shock. The addition of potassium sulphate to the local anæsthesia solution will lengthen its effect. Morphine in transport is employed to ward off pain and shock. Its use protects the brain cells from continued painful stimulation. Saline infusion with the addition of adrenalin is useful in shock after hemorrhage otherwise pituitary extract should be used.

At the base hospitals patients are examined as to their general condition, the temperature and the pulse rate. If they are comfortable they should be allowed a period of rest unless there is evidence of gas-gangrene. Compound fractures are X-rayed and when necessary to remove the dressing and splints these should be reappplied under anæsthesia.

Extensive lacerated wounds without fracture should be put at once into a saline bath with the addition of eusol when the discharges are very offensive. This is good for sepsis and it avoids pain. It helps frequent redressing.

Shock is prevented by warding off the conditions that cause it: pain, sepsis and hemorrhage.

Pain is relieved by proper dressing, proper fixation, and the use of morphine. Sepsis is avoided by ample drainage.

When shock is caused by loss of blood saline solution should be administered at a temperature of 71.2 F with 10 to 20 drops of adrenalin to the pint into the rectum, cellular tissues or a vein if the symptoms are urgent.

Before operation morphine given with atropine should be administered hypodermatically. If the patient is to undergo any severe operation, local and regional anæsthesia should be employed. For this purpose one may use infiltration with novocaine per cent with adrenalin chloride added. If to this is added potassium sulphate gr 10 to each ounce the anæsthetic effect is prolonged and pain after operation is lessened. The use of urea and quinine is sometimes employed by Crile for the same purpose in lieu of potassium sulphate. Instead of infiltration around the main nerve supply infiltration in the cauda equina may be employed for the benefit of cases of operation on the lower extremities. In

filtration of the tissues should be done with a large syringe so that force may be exerted to distend all the lacerations and this may be facilitated by making an incision with the hand.

Cutting with a sharp knife causes less shock than tearing with an ill manipulation should be gentle. Oxygen may be used in the flap and the patient's head held below.

After operation the usual methods to maintain blood pressure with renthol of the patient should be resorted to.

In early first aid treatment is the application of the first aid dressing, namely, a sterile gauze pad held in place by a bandage. It may have been applied by a regimental surgeon but is often by a stretcher bearer or a patient's comrades. This dressing has been found to prevent further infection of the wound in the field.

While in the field first aid men use the gauze bandage, but in the hospital the use of a powder gauze or solution. The gauze will penetrate and act at a distance. The powder and solution are harmless to the tissues and do not become putrid against bacteria and the pores. The effect of this antiseptic is purely local and hence no danger to be apprehended from absorption. It promotes lymphatic drainage and controls infection. The powder can be introduced in the first aid dressing. When water is available it can be made into a solution for general use. The constituents of the powder are inexpensive and easily procured and its preparation is very simple.

The removal of the first aid dressing is done at the field ambulance at the earliest moment practicable the earlier the better. In superficial wounds the dressing is removed by the surgeon who wears rubber gloves the part are cleansed with ether and then laid on a clean towel. The surrounding surface and wound are painted with a 5-per-cent solution of iodine and the wound is then dressed with iodoform gauze.

A wet dressing is used in more extensive foul wounds and a large drainage tube should be placed in the depth of the wound. Deep wounds may require drainage by counteropenings and the use of immobilization is always in order for fractures and extensive wounds.

The application of dilute antiseptics to a wound will only reach the organisms that are disposed on the surface. In order to reach deep infections one has to practice thorough drainage and wash out the remote recesses with weak antiseptic solutions such as a 1-per-cent tincture of iodine, 1-per-cent carbolic acid, 1-1000 mercuric iodine or 1-1000 mercuric chloride in dilute form.

Ample drainage with the application of hydrochloric acid in the form of eupad or repeated irrigations with eusol has proven one of the most efficacious agents in the penetration of anaerobic infection in the present war.

Eupad is a powder consisting of equal weights of bleaching powder and powdered boron acid in

dy mixed. Wounds which are packed with e impregnated with the powder are stimulated the escape of hydrochloric acid gas, which is a rful antiseptic. Congestion and oedema are cured. After a few applications th antiseptic moved and hypertonic salt solution is subtit-

col is prepared by shaking up 5 gm. f eupad oe liter of water, after standing for a few hours solution is then filtered through cloth or filter

ne method of using the two forms of hypotonic acid in accordance with present experience follows

Eusol which is a standard strength of approximately 0.5 per cent hypochlorous acid, may be used as a solution diluted with water or normal salt, as a fomentation covered with a water proof ring (c) on gauze without a water proof cover (d) as a bath, full strength y diluted.

Eupad is used when it is desired to apply a concentrated antiseptic as follows. The wound cked with gauze with the powder between the s when the fabric is dampened with w ter dressing is then covered with wool and band-applied as above and covered with a water-proof ring f r only ot 20 min ten as rule. When occurs a weaker application should be employed rands of gauze or wool impregnated with the ter and used as drainage or as a dusting powder plet sores.

become clean and can be made to heal like aseptic fractures.

The principle element of treatment of large septic wounds is the establishment of adequate drainage and the removal of foreign bodies and dead tissue. The latter may be removed by cutting away with scissors or by curetting. The whole wound may be excised with advantage in some cases.

Wound drainage an important factor in the treat ment of wounds is practiced more satisfactorily at the base hospitals. The drainage should be provided with all necessary counteropenings. Rubber drainage tubes are preferable to gauze drains, which are apt t clog. Loose woven cotton bandage is better than gauze. One end of the bandage is placed in the wound and the other is carried in a bowl containing a little saline solution. Th wound is kept wet either by an irrigation drip or by fre quently pouring saline int the wound, and when dependent counteropen g has been made split rubber drainage t be is passed through the wound and the bandage is mad to slip along side of this tube

Irrigation of wounds assures a more steady meth od of f eeing the wound of toxic matter and to this end the osmotic action of hypertonic solutions is taken advantage of. The flow f saline in and out of the wound continuously removes the film of toxic matt and the aby limits t ne absorption. The wounds found most suitable f r treatment by con tinous irrigation are impound fractures and deep septic wounds, especially of the ppe arm and thigh. Fomentati as of bot bon acid may be alternated at times with the oth methods of treatment espec ally when the w u ds become at glish in healing

The bath treatm nt of wou ds induces healing by increasing the blood supply to th part. Regions like the face rich in blood supply heal faster than other part ilk the feet for instance. Hypertonic solution has t great extent replaced the antiseptic bath and it is deafo wounds, f the limbs below the elbow and knee. Continued too lo g t renders the tissues sodden and n dring to the patient, nd it is ot p actured with patient in serious condition. The bath may be alternated with fomentations at night or it may be replaced by irrigations in th day.

The open treatment of wounds consists i placing a laye of wet gauze over the wound in lieu of the old gauze wool nd bandage which acts as a septic poult ce

T eatment f M wounds by excision. The treatment of compound fractures cranial and joint ounds has been very much modified by the employ ment of excision. The sooner the excision is made the better because later a large bank of inflamed infected tissue surrounds the wound. In such cases hypertonic solution will render the wound ready for operation in 4 t 48 hours. Co tra-indications to excision are marked pocketing in the wound and the exposure of vascular or nerve-trunks or of bone, hich it is inadvisable t remove. In any case excision f the eiled edges f the kin superficial tissue and

Hospital at Constantinople during which time they made 222 surgical interventions.

Among the 222 operations were 9 amputations 4 of the upper arm, of the thigh 4 of the lower leg; 16 resections, 5 of the knee-joint, 6 of the ankle joint, 3 of the shoulder joint, 1 of the elbow, 1 of the wrist, 3 exarticulations, of the phalanges of the thumb 2 of the shoulder joint, 11 cranial trepanations, 4 vascular operations (ligature of the brachial) for periphrastic septic hemorrhages, 2 previous to exarticulation operations, 2 resections of ribs, 5 laparotomies (3 of these cytotomies) enucleations of the eye.

The other cases included incisions, curettings, sequestrotomies, luxations, reductions etc. There were also some epididymectomies, and testicle resections for infections. The operative mortality was 11.25 per cent, 5 deaths. In the 9 amputations 8 died, 4 2 per cent—2 upper arms, 3 thigh, 3 lower leg. Of the 16 resections, 8 died, 11.75 per cent—of the knee-joint, of the shoulder. Of the laparotomies, 8 died, 80 per cent. Of the trepanations, 3 died, 7 per cent. The other 11 deaths were in typical operations and are not specially enumerated.

There were 6 cases of gaseous gangrene, 4 of cerebral abscess, 6 suppurating fractures, case of projectile extracted from the bladder. As general rule all these wounded arrive in the hospital in a more or less infected condition. Of the cases of gaseous gangrene 3 occurred in amputations, 1 with amyloid degeneration for empyema. In one case it was necessary to amputate 3 days after a resection. The authors think that in cases of doubt between resection and amputation, as the organic resistance is very low it is better to resort to amputation at first because it is better to lose a limb than a man.

W. A. BREWSTER

Leriche, R. *Integral Operative Statistics of Surgical Service at the Rear* (Statistiques opératoires intégrales d'un service de chirurgie de l'arrière). *Lyon chir.* 9 6, xlii, 193.

In the two rear hospitals of which Leriche had charge 99 wounded were received between September 10th, and October 15th, 915. All those received and operated upon within twenty-four hours of injury recovered. The others were mostly received from two to five days from the line of injury and of these 7 died.

All the wounded had received antitetanic serum at the front. All later received a second injection and even a third where there was a late intervention. No case of tetanus developed.

There was only one case of gaseous gangrene. This was in a man who had lain five days on the field. He was cured.

Of 88 cases which the author considers definitely cured 133 have recovered their physical strength almost completely, 55 have a physical value more or less diminished—loss of a limb, eye, etc.

W. A. BREWSTER

Cutler F. J. *The Surgical Disabilities of Troops in Training*. *Preadmirer* Lond. 9 6 xvi 359.

A large number of mutilating gunshot wounds of the face have occurred during the present war. Many of these have been complicated by fracture of the mandible. The usual method of treatment is by wire splints fastening the teeth in position. So many of these cases however result in loss of bone either from immediate destruction or from subsequent infection, that it is often necessary to fill in a considerable gap in the mandible. This is best accomplished by transplantation of bone. The wounds must have soundly healed and all septic or damaged teeth removed from the neighborhood of the fracture some time previously. A portion of a rib is then accurately fitted into the gap fastening it there either by wire tacks or by silver wire.

It would seem that this transplant acts mainly as a scaffold for the new bone forming cells, but a case reported by Albee would indicate that the transplants themselves have power of bone degeneration.

J. H. SMITH

Latarjet, A. *The Working of Clearing Ambulances* (Le fonctionnement d'une ambulance). *L. chir.* 9 6 cli 166.

The author gives very interesting particulars of the surgical work done in a field ambulance during the period of offensive. To this ambulance service was assigned the work of receiving all the wounded from an army corps. During the 5 days of attack, 9,358 wounded were disposed of. Of these 5,012 were slightly wounded, and 4,346 had more or less grave wounds.

Of the 5,012 slightly wounded, 4,666 were immediately dispatched to the clearing hospital. The remaining 4,355 were examined and had their wounds dressed. These wounds comprised

Head and neck	73
Thorax	354
Abdomen	102
Upper limbs	1600
Lower limbs	1310
Multiple wounds	46
Shock	91

After the wounds were dressed these men were sent on to the clearing hospitals at the base. The 4,317 injuries of the seriously wounded were as follows:

Head	56
Neck	96
Thorax	531
Abdomen	267
Upper limb	816
Lower limb	1443
Spine	18
Genital organs	24
Multiple wounds	365
Gas intoxication etc	41

Of these 4,317 308 died during the period within five days, mostly a few hours after arrival and with-

out intervention. Sixty three died while being conveyed from the field to the ambulance. The total immediate mortality was 254.

Of the 531 thoracic wounds 176 were shell wounds, 132 bullet and 9 bomb wounds. Twenty three died between the first and third day from hemorrhage or shock. 16 died from the fourth to twelfth day. Of the 26, abdominal wounds 124 were penetrating. Two hundred and fifty four of the wounded intransportable and inoperable were hospitalized on the spot. The others were dispatched to the clearing base hospitals, either by auto or train.

Hospitalization within a few hours of injury immediate large evacuation of wounds and evacuation only toward the interior when the patients are in a fair way to recover are the ends to be sought if lamentable consequences are to be avoided.

SURGICAL PATHOLOGY

Bristol L. D.: Free Tumor Diagnosis as a Function of State Public Health Laboratories. *J. Am. Med. Ass.* 19 6 1vi, 678

The results of investigation show that for pathological examinations in state laboratories of the 48 states 24 have facilities for the diagnosis of suspected cancerous tissue either in their state public health laboratory or in some other state institution while 24 do not attempt such work.

Of the 24 states which have facilities for making tumor diagnoses 5 charge specified fees 6 charge all persons except indigents and 13 make no charge in any case.

From information available it seems that opinions of authorities differ somewhat as to whether or not tumor diagnoses should be made free of charge either by state public health laboratories or other institutions as an important aid in the campaign against cancer.

The chief arguments received against the free diagnosis of tumor tissue in state laboratories are as follows:

1. Diagnosis of tissue for cancer is merely a private consultation and is not regarded as public health work.
2. The plan would savor too much of state medicine.
3. As a rule the appropriation for the state laboratory does not warrant the doing of more work and tumor diagnosis should not interfere with the diagnosis of the so-called communicable diseases.
4. There is danger of spreading cancer-cells into other parts of the body by the excision of small specimens for diagnosis.

The following recommendations are submitted as worthy of consideration in the campaign against cancer.

1. So far as consistent with local conditions facilities should be offered under public auspices in each state for the diagnosis of tissue suspected

of being cancerous. Preferably these should be made free of charge.

2. The logical place for doing such work is the laboratory of the state health department. It is not to be supposed that such work will be given preference over other work now being done by these laboratories.

3. To cover this work in those states which have no such facilities additional money should be appropriated.

4. Judgment must always be used by surgeons in the removal of suspected cancerous tissue for diagnosis and the value of a microscopic diagnosis should appear to outweigh the risk involved before such a procedure is adopted.

EDWARD L. CORWELL

Birch F. W.: A Group Study Plan for a Diagnostic Team Acting as a Laboratory for the Profession. *J. Am. Med. Ass.* 19 6 1 i 67

St. Luke's Hospital, San Francisco is the only institution reported to have organized specialists to act as a laboratory for diagnostic purposes returning the patient after investigation to the referring physician with a protocol of the findings and recommendations for the treatment of the case.

This new era in medicine is very young; the medical universities are not yet teaching this type of medicine; they have not even accepted it and in fact there is no definite instruction to be had on the subject. The method of group study now employed in hospitals by referring the patient from one department to another without joint discussion of cases by the heads of these departments is open to as severe criticism as that which Doctor Cabot applied to the methods of the general practitioners.

It has not been long realized that the three great classes of patients, the rich, the poor and the middle class are receiving quite different medical attention. The rich man while he is able to pay for the services of a large number of high priced specialists presumably gets the best medical consideration but unfortunately the highly paid specialists are individuals who are not organized and their work is not correlated; consequently consultations are often perfunctory and unsatisfactory to both physician and patient.

The diagnostic section of St. Luke's Hospital, San Francisco consists of ten men, each having special training along some particular line. The members of the profession refer obscure cases to this section for diagnosis. These patients are placed in the hospital for observation and each member of the diagnostic team makes an individual examination and a written report of his findings. At noon each day the team meets to discuss the cases. If the case is not clear at the first consultation further investigation is recommended and any new discoveries are reported the following day. This method of procedure is continued day after day until some conclusion is reached. The physician

who referred the case is asked to be present at all of these consultations. Finally the patient is referred back and a written report of the findings and recommendations for treatment are mailed to the attending physician. Thus the specialists make of themselves a diagnostic laboratory.

All of this work is being done by the diagnostic team for a fee commensurate with the patient's income. The amount collected is not sufficient to pay for the time of the clinicians. However the good that is being accomplished by this method of study and the educational returns for each member of the team in daily discussion with his colleagues amply repays the clinicians.

The success of a plan of this kind depends, briefly on the following conditions. The diagnostic team must accept from the professional case for investigation at a price consistent with the income of the patient. Cases should be examined by all the members of the team, the results of their findings must be written, the specialists meet in daily consultation over the cases, and investigations continue until all possible evidence is discovered. The case is returned to the physician who sent it and a report is mailed, together with the conclusions and suggestions for treatment.

The results to be expected from such a scheme are these. The general practitioner will gladly accept it, the good influence of the family physician will be preserved, medical men in the community will take advantage of the daily discussions and gradually broaden their point of view of medicine, this method of group study will maintain the advantages of specialization and do away with the disadvantages. Clinical reports from this work bearing on these predictions are now being prepared for publication.

EDWARD L. CORRELL.

Binnis, J. F. The Role of the Sympathetic System in the Diagnosis of Abdominal Diseases. *Am. J. M. Sc.* 9 6, 631.

The phenomenon of pain or tenderness in acute abdominal diseases occurring in a situation different from the diseased organ, for example, the median line pain in early appendicitis — commonly spoken of as reflex pain — is explained by the author on the basis of development and physiology of the sympathetic nerve supply of the region.

Reviewing the embryology of the abdominal viscera, he points out the median position of organs (and therefore of the nerves supplying them) which later migrate to lateral positions, but their nerve supply maintains the original median connections. The anatomy of the abdominal and thoracic sympathetic system is reviewed in detail and its connections with spinal nerves, pneumogastric, phrenic, etc. are recalled. Periumbilical pain in the peritonitis is explained through the distribution of the right phrenic nerve which sends fibers to the diaphragm, liver and anterior parietal peritoneum as low as the umbilicus. The connections of the right phrenic with the lower intercostal

nerves, through the diaphragmatic plexus, explain right-sided abdominal pain in thoracic diseases, e.g. empyema or pneumonia.

Referred pain is due to the increased number of afferent impulses from an irritated organ coming to the nerve-center which is unable to handle them in the normal way and the result is a radiation of the afferent impulses along the trunks of the sensory nerves, passing near the center giving rise to a sensation of pain at the nerve-endings. If a motor path is affected the result will be muscular rigidity.

The phenomenon of crossed pain tenderness of the superficial sensory nerves, difference in protopathic and epipathic sensibility in abdominal inflammations with the resulting clinical signs, are described in detail.

The author discusses the more recent work by neurologists on the causes and nature of abdominal pain due to irritation, distention, etc., and explains the origin of secondary pain or that arising through extension of the irritation beyond the organ first affected.

That renal pain is not midline is due to the lateral development of the kidney. Renal irritation as in ascites, therefore does not give rise to epigastric pain. The occurrence of atonic contraction of the anal sphincter due to renal irritation and causing symptoms of intestinal obstruction is explained also the role of the sympathetic system and the phenomenon of radiation in genito-urinary organs, especially in prostatic disease is elucidated.

HONORÉ BERRY.

Stoddard, J. L., and Cutler, E. C. Torula Infection in Brain. *Monographs of Rockefeller Institute for Med. Research*, 9 6, N 6 Jan., 31.

Two cases from the Cushing's clinic at the Peter Bent Brigham Hospital presented at autopsy unusual lesions in the brain and meninges. The histories and physical examinations included such signs of cerebral tumor as to indicate decompression or exploratory operation, but the pathological examination in each case proved the complete absence of tumor. Lesions were found, however which fully explained the clinical symptoms and physical signs. Enormous numbers of organisms having many points of resemblance to those of blastomycosis occurred in all of the lesions in such a manner as to leave no doubt of their causal relations. Certain differences from the usual descriptions of the organisms of the blastomycosis group and their lesions made a careful study necessary to determine the relations of the authors' cases.

Two problems which have received increasing attention in late years, without great progress toward their solution, were thus brought to the author's notice by the study of the cases. I.e. the problem of cerebral pseudotumor and the problem of the relationships of the lower fungi forming the group called blastomycosis. It seemed probable to the authors that their cases might throw light upon both these questions.

In the study of the first problem that of pseudotumor cerebri, the literature furnished a considerable number of cases in which symptoms and signs of brain tumor existed for a short or long time with subsequent recovery or with indefinite autopsy findings.

In trying to solve the other problem, that of the relationship of the organisms of the blastomycosis group they studied the literature and made animal experiments. In their experiments they used pure cultures of three different organisms one isolated from a human case of cutaneous blastomycosis one from a human case of coccidioidal granuloma and one from Frothingham's case of torula infection in a horse. Inoculations were made in various ways upon several species of laboratory animals and agglutination experiments done upon the infected animals.

One of the problems in the authors' work was the relationship of the organisms causing the diseases termed blastomycoses. They have shown the confusion existing in textbooks where the various diseases are described as one disease or as different manifestations of the action of a single organism in different states. The study of the literature convinced them that coccidioidal granuloma was a disease distinct clinically pathologically and biologically from other diseases called blastomycosis. Having decided that coccidioidal granuloma was a distinct disease, they turned their attention to the blastomycoses. They found in the literature two cases of skin and general infection produced by a true yeast with endospores in culture. Both cases were observed by Buschke and appeared to be distinct from the American cutaneous disease. Frothingham's discovery of torula infection in a horse indicated another type, but no such cases had been reported in human beings.

The authors' cases were distinct from the larger part of the reported cases of blastomycosis in their clinical histories and pathology. It did not seem improbable to them that in the early study of blastomycosis such cases had been described, but their nature not recognized. They studied the original reports of all the cases of systemic blastomycosis and found that nearly all the cases were similar so far as could be ascertained from the printed reports except those involving the brain. Among

these there were obvious differences. First there were six cases like the other systemic cases but in which the brain became involved as part of the general infection which always included skin manifestations and often bone lesions. The symptomatology was not perceptibly influenced by the brain lesions. The pathology of the brain lesions resembled that of the other lesions. Different from these were four cases in which there were no skin lesions but in which a general infection occurred with brain lesions which caused the predominating symptoms. Pathologically the lesions were distinct in many ways but principally in the extension by solution of tissue the always chronic reaction and the production of a gelatinous material in the lesions.

Their first case was evidently identical with this latter group. Their second case was not fully identifiable by the study of the literature alone for the peculiar intracerebral lesions were not present and the parasites occurred in greater numbers of small forms. Such forms occurred in the meninges of the first case but not in the intracerebral lesions and were not described in the literature. In the experimental meningitis in a mouse produced by the injection of a culture of the ventricular fluid from the second case however large organisms were produced identical with those of the first case and intracerebral lesions of the same type were seen in process of formation. Thus their two cases proved to be alike in origin. Frothingham's case of torula infection was evidently the type of infection of these cases. In their animal experiments with torula the authors found both forms of parasites present in the lesions in varying proportions according to the extent and activity of the process. In a very active lesion enormous numbers of small organisms similar to those of the second case occurred these were seen especially in the meningeal lesions. In older lesions tending toward recovery or in those slowly progressing and in the higher animals the larger forms predominated. In sections of the original horse lesions small forms were entirely absent. Their experiments resulted in the production of all the variations in lesions and organisms seen in the cases. The animal experiments thus provided the necessary steps for the clear correlation of all the human cases as cases of torula infection.

GEORGE E. BERLEY

GYNECOLOGY

UTERUS

Stein, A. The X Ray Treatment of Uterine Myomata; a Warning Based on a Study of the Literature. *Med Rec.* 9 6 XXXX 99

Stein sounds a warning to the enthusiast on the X ray treatment of uterine myomata and has thoroughly reviewed the literature of this subject citing numerous instances to substantiate his contention that the X ray does not accomplish all that is claimed for it.

Since according to Klein, 77 per cent. of uterine myomata show malignant degeneration in some form, how is it to be determined whether one is radiating a malignant tumor or a simple myoma? As a matter of fact, the author continues, at the present state of our radiological knowledge we have a perfect right to take for granted that the X rays may set up proliferative changes of a degenerative character in those areas of a radiated myoma which are not destroyed by the treatment. Furthermore, women in the child-bearing age may have their functioning ovaries badly crippled or even destroyed, thus endangering later offspring through changes of the germ plasma produced by extensive radiation. Sterility is common following long exposure to the X rays.

The author calls attention to the difficulty in selecting suitable cases for diathermy and cites a case of interstitial pregnancy with profuse hemorrhage who was given the choice between radiation or operation for myoma of the uterus. Fortunately the patient chose operation. She made an uneventful recovery whereas, otherwise a rupture of her interstitial pregnancy might have meant sudden death.

Injuries directly traceable to the X-ray treatment of intra-abdominal lesions are practically unavoidable. Multiple peritoneal adhesions, deep ulcers of the abdominal skin, sclerotic changes of the pelvic connective tissues, irritative conditions of the bowel and bladder, atrophy of the gastro-intestinal glands are conditions of lesser importance which may result from continued radiation.

In conclusion the author says judiciously restrained the indications for the X ray treatment of uterine myomata are very limited, including besides myoma patients who have reached the climacteric, those suffering in addition from diabetes, obesity, advanced arteriosclerosis or hemophilia, in whom surgical interference involves serious danger to life.

HARVEY B. MATTHEWS.

Crossen, H. S. Choice of Operation in the Various Classes of Cases of Retrodisplacement of the Uterus. *J. Ma. St. M. Ass.* 9 6 XII, 260.

The author has endeavored to make clear the method which should be employed to hold the uterus in anterior position.

A dependable presentation of this subject implies a careful consideration of the various operative measures devised and their adaptability to the correction of the pathologic condition present in different patients. There is considerable confusion at the present time and for the very good reason that there are certain factors in uterine support not yet fully understood even in physiologic conditions and much less in pathologic conditions.

The following according to the author may be taken as a safe working basis:

1. Most of the symptoms in retrodisplacement of the uterus are due to complicating conditions. Therefore such conditions must be treated first and the treatment of the retrodisplacement will depend to a large extent upon the complications.

Normally the uterus is held in position by a combination of structures. Therefore, in any scheme of restoration, either this combination support must be restored or other structures utilized to bring about a similar support.

2. Pelvic floor support is absolutely necessary to the permanent correction of any retrodisplacement.

3. When decided prolapse of the uterus can be excluded the problem, after treatment of the complications, resolves itself into maintaining the corpus uteri in the anterior position and the cervix in the posterior position of the pelvis, with sufficient elevation of the uterus and adnexa to prevent dragging on hypersensitive attachments.

4. As this problem varies with the different pathological conditions present, it is advisable for purposes of study and comparison to group the cases into classes somewhat as follows:

A. Future pregnancy possible.

- (1) Adnexa intact—tissues freely movable.
- (2) Ovary and tube of one side removed.
- (3) Tube only removed.
- (4) Ovary only removed.
- (5) Diffuse tissue infiltration, fixing ligaments.
- (6) Varicose veins of the broad ligaments.
- (7) Cervix too far back.

B. Pregnancy not possible.

- (1) Active uterus preserved.
- (2) Scirrhous uterus preserved.

6. For maintaining the corpus uteri in the anterior position there are a number of fairly satisfactory intra-abdominal methods which utilize one or more of the ligaments supporting the uterus.

7. In general, it may be stated that vaginal operations for retrodisplacement is indicated in those cases where other deep vaginal work is needed and lesions requiring abdominal section can be eliminated.

HARVEY B. MATTHEWS.

ADNEAL AND PERIUTERINE CONDITIONS

Heineberg, A.: Tubal Sterilization Pregnancy Following Bilateral Salpingectomy: A Report of Two Cases and a Complete Review of the Literature. *V F M J* 1916 cll 107

The author reports two cases of pregnancy following bilateral salpingectomy where the tubal stumps were merely ligated. With this report he presents a careful review of the subject in its surgical phase discussing the various surgical procedures that have been developed.

He offers the following conclusions:

1. There is no method of tubal sterilization which affords absolute security against conception.
2. Simple ligation of the fallopian tubes with either single or double ligatures has been followed by the largest number of reported failures.

3. Excision of a wedge-shaped section from each cornu of the uterus, followed by careful closure of the opening with musculomuscular and seroserosus sutures has yielded better results than any other method.

4. In the light of our present knowledge it seems unwise to advocate any other method than cornual resection. The conclusions are in accord with those arrived at in previous reviews of this subject.

CAROL CULBERTSON

Long, J. W.: Shivering the Round Ligaments. *Is S'g Phila.* 1916 lill 690

To the multitude of operations already devised for the correction of backward displacement of the uterus the author adds another for which he claims simplicity and efficiency. It consists in grasping the round ligament near its middle with a forceps and making traction upon the distal portion. While this tension is held a round needle armed with linen or silk, is thrust through the ligament close to the pelvic brim just as it leaves the inguinal canal. The needle is then put through the ligament by an over-and-over stitch about every quarter of an inch until a sufficient amount of the ligature to insure a proper degree of shortening has been included. The last puncture of the needle usually passing through that portion which has been transected by the forceps. By pulling the two ends of the ligature together the ligament is shirred and the necessary shortening produced. In addition to this the author has found that traction on the suture develops a small *mesoligament* which springs from the pelvic wall. This piece of peritoneum may be well utilized to cover over the shirred portion of the ligament. The same suture may be used for the entire operation.

GATEWOOD

EXTERNAL GENITALIA

Gittings, J. C., Hamill, S. M., and others: A Report of the Committee on Vaginitis. *A Ck Pediat* 916 xxiii, 351

This committee appointed to investigate the subject of vaginitis in infants and young girls

conducted a very thorough investigation. A questionnaire was sent to various institutions caring for female children and to a large number of pediatricians. With these replies as a basis they formulated the following set of resolutions:

1. That cities be required to provide adequate hospital and dispensary facilities for the care and treatment of children having vaginitis.

2. That matrons be placed in charge of the girls toilet rooms in public schools.

3. That toilet seats embodying the principle of the U shape be used in all schools and that the toilets be of proper height for different ages.

4. That city and state laboratories be empowered and equipped to make bacteriologic examinations for physicians when patients cannot afford to pay a private laboratory fee.

5. That educational literature on the subject of vaginitis be prepared and distributed to mothers through the medium of physicians, hospitals, dispensaries, health centers, municipal and visiting nurses.

6. That asylums for children and day nurseries be licensed and that the license be not granted unless first the institution has adequate facilities for the recognition of gonococcus vaginitis and second that the institution exclude children having this disease if they cannot be properly isolated.

7. That separate wards be maintained in hospitals for the treatment of children with vaginitis who are also suffering from other diseases.

8. That microscopic examinations of smears be made before admission to the general wards of the hospital. In securing material for the smears extreme care should be taken to observe rigid aseptic precautions.

9. That observation wards be provided.

10. That individual syringes, bed pans, catheters, clinical thermometers, thermometer lubricant, wash basins, soap powder, wash cloths and towels be provided.

11. That single service diapers be used (at least for girls) or that diapers be sterilized in an autoclave at 15 pounds pressure for five minutes.

12. That nurses be required to make daily inspection of the vulva of each at the time of bathing and to report immediately the presence of the slightest suggestion of a vaginal discharge.

13. That low toilets be provided and equipped with seats embodying the principle of the U shape.

14. That for routine purposes, the spray be used in place of tub-baths for the bathing of young girls and that older girls be sponged in bed.

15. That nurses receive special instruction as to the nature of vaginitis, the ease with which it is transmitted, the methods of preventing its spread and the necessity for rigid aseptic surgical technique in its handling and treatment.

16. That a dispensary with special facilities for the treatment of gonococcus vaginitis be provided.

17. That nursing care and supervision be given in the home.

18. That mothers be instructed as to the dangers of vaginitis, the manner in which it is transmitted, the best method of protecting other children, and the necessity of prolonged observation.

19. That all cases of vaginitis under observation be voluntarily reported to the local health officer in states or cities where no legal requirement are in force.

EDWARD L. CORRELL.

MISCELLANEOUS

Watkins, T. J. *Diagnosis in Gynecology*. Chicago. *McGraw-Hill*. 9 6, xxviii, 359.

An analysis of abdominal palpation shows that it is always relative, that the findings are estimated by comparing the resistance to pressure over various areas of tissues or organs. By comparison only can a very soft pregnant uterus, a distended bladder or cyst with fluid wall be at times detected by palpation. The palpation should always be light, as firm pressure lessens the tactile sense, causes pain and excites rigidity. Observation of the facial expression is of great value when palpating for tenderness.

The technique of kidney palpation consists of the use of delicate vibratory palpation, such as is employed in bimanual examination of the uterus and ovaries. One hand is placed just below the ribs posteriorly and presses the kidney gently forward with the other hand delicate vibratory counter pressure is made anteriorly over the region of the kidney.

Greater tenderness over the region of the appendix than over the corresponding region on the opposite side is diagnostic of chronic appendicitis, other demonstrable pathology being excluded. Absence of tenderness does not exclude appendicitis, as gross pathologic changes in the appendix are frequently found in the absence of tenderness. Atrophic changes (appendicitis obliterans) (Sen) are accompanied by increased tenderness in about 50 per cent of cases. Palpation over the region of the appendix in all gynecological patients is highly important, as experience has demonstrated that the appendix is diseased in a very large percentage of cases with extensive pelvic pathology.

Valuable information is obtained from vaginal inspection and palpation. Urethrocele is frequently not detected and the method of diagnosis is not generally known. Urethral ocele is essentially a downward and backward displacement of the urethra. Urethrocele is detected by pressing the urethra upward toward the cervix, and the distance it can be so displaced represents the extent of the lesion, as it is normally quite fixed.

The position of the uterus can often be determined by the appearance of the cervix. When the anterior lip of the cervix is much thicker or longer than the posterior the uterus is almost invariably in anterior position. The same rule applies to the posterior lip of the cervix.

Palpation of the uterosacral ligaments for tenderness is important as it often helps determine the degree of pathology of a retroposed uterus.

A most difficult class of gynecological patients to diagnose are those with pelvic pain without well defined pathology. Mistakes are commonly made in such cases, as the pain may be due to pathologic states that cannot be detected on pelvic examination, or the patient may have or complain of pain without the presence of pathology in the pelvic organs. It has been found that the pain from adhesions is chiefly due to traction upon the peritoneum. It is, therefore, easy to appreciate that any examination which will put such adhesions on tension will be attended by pain. This fact can be utilized in the diagnosis of such cases.

The low mortality of abdominal section tempts the surgeon to operate for pelvic symptoms without making a careful diagnosis, and for pelvic symptoms without demonstrable pathology. Surgery has developed beyond the time when the results of operations should be based upon mortality. The real test of modern efficient surgery is morbidity.

The considerable danger of occasionally mistaking a large corpus luteum for a small ovarian cyst and of thus subjecting the patient to an unnecessary operation. The corpus luteum at times attains a size two or three inches in diameter due to hemorrhage or edema about the gland. On careful palpation it is impossible to distinguish it from a small ovarian neoplasm. The diagnosis should be made by constantly keeping in mind the possibility of a large corpus luteum in the diagnosis of all ovarian tumors and keeping them under observation a sufficient length of time to allow absorption in case of corpus luteum. A lapse of one month is probably long enough to establish a differential diagnosis.

EDWARD L. CORRELL.

Bello, A. *Menstrual Fistula of the Abdomen* (Fistula menstrual del abdomen). *Rev. Assoc. Med. Argent.* 9 6, xii, 4.

The case reported by the author occurred in a woman of 36 showing symptoms of tertiary syphilis. The uterus was anteflexed with both annexes enlarged and the uterus between them inflamed and painful and showing a prominence in the left iliac fossa without any modification of the skin. Exploration of the fossa disclosed nothing of importance. The wound did not close but established itself as a cutaneous fistula through which there was an abundant flow of blood during the periods and a flow of pus in the intermenstrual epochs.

The fistula persisted in spite of all attempts at treatment, and laparotomy was done. The epiploon and intestinal loops were adherent to the left uterus and annex. The uterus was fibrous and twice the usual size and adherent to the bladder. The right annex was cystic. The tube of the left annex was largely cystic in the ampullary region. The first part of the tube led to a fistula which was located in the abdominal wall at the left of the median line.

A subtotal hysterectomy was done with ablation of both annexes. A portion of the epiploon was

resected and the fistulous tract closed by sutures. Recovery followed. W. L. BRENNAN

Stevens T. G.: Adenomyoma of the Rectovaginal Septum. *Proc Roy Soc Med* 916 1x Obst & Gynec Sect 1

The author refers to cases described by Lockyer, Spencer, Lelich, Bland, Sutton, Gough and Stewart and to his own case previously demonstrated in 1909.

During the preceding eighteen months he has had under his care five more cases. These are tabulated in detail and illustrated. In the fourth of these cases the anterior rectal wall had been so involved as to be drawn up in a double fold without however invading the rectal mucosa. In this case there was also present a cyst of the vaginal wall undoubtedly of Gartnerian origin.

Stevens notes that the symptoms varied. In one case they were menorrhagia and dysmenorrhoea. In two cases sterility was the only complaint. In the other three bleeding was the chief symptom due in one case to fibroids in the body of the uterus in another to chronic metritis and in the last to some unexplained general condition associated with the menopause.

The growths are all situated in the loose connective tissue above the posterior vaginal fornix, bounded anteriorly by the back of the cervix, posteriorly by the rectum, above by the peritoneum. They present hard nodular masses fixed to the back of the cervix and movable with it. They are not tender to the touch and cause no pain. The rectal wall may be involved but the rectal mucosa never.

Microscopically these growths show precisely the same structure as a diffuse adenomyoma of the endometrium but as a rule the gland tubules surrounded by endometrial stroma are few in number. The tubules are often dilated and cystic, not infrequently containing blood or blood pigment. The surrounding stroma is composed of cell elements exactly like the stroma of the endometrium. The fibromuscular part of the tumor is clearly a definite new growth. Although there is no capsule the arrangement of the fibromuscular tissue is such that the growth is quite sharply marked off from the uterine muscle coats. There is perhaps more fibrous and less muscle tissue in the growth than in the uterine wall. In none of the specimens was anything found to suggest an inflammatory lesion.

The author discusses the various theories regarding the origin of these tumors and holds as untenable his original view that they are derived from wolffian remnants. The possibility that they are derived from the muellerian ducts at the place where the fused ducts join the solid mass of cells from which the vagina is developed cannot be disproved.

CAREY CULBERTSON

Montanari E.: The Pathogenesis and Treatment of Genital Prolapse (Sulla patogenesi e sulla cura del prolasso genitale). *Clinica* 96 vii 223

The author passes in review and criticises the various methods in vogue for the treatment of

genital prolapse. He does not believe that vaginal or abdominal hysterectomy can ever be considered an ideal method but only a procedure of necessity inasmuch as such operations produce a grave and irreparable mutilation hence the method should not be used on a young woman with a normal uterus.

Treatments limited to the vagina, such as colpoperineorrhaphy and similar operations are insufficient and interfere with coitus while they do not obviate the anatomopathologic alterations which were the principal cause of the genital prolapse.

The author insists that genital prolapse is chiefly due to inequality between the resistance of the peritoneum and endo-abdominal pressure such inequality being determined either by a congenital or an acquired weakening of the support and stability of the uterus and especially of the soft framework forming the pelvic floor. As a surgical procedure the author considers the operation devised by Ruggi to be the most efficacious and rational for the treatment of total prolapse in women within the active period of sexual life.

The main points in Ruggi's operation are as follows:

1. A circular incision above the normal position of the fornices two incisions perpendicular to this on the two sides of the anterior vaginal column these incisions being turned off at the ends. Three flaps of mucosa are thus formed the central from the anterior vaginal column and two quadrilateral side pieces. The neck of the uterus is drawn out and isolated. The two lower thirds of the lateral walls of the uterus are sutured with catgut to the base of the broad ligaments.

2. Obliteration of the uterovesical and uterorectal cavities suturing the uterine fundus with fine catgut to the peritoneal sac which covers the posterior face of the bladder replacing the uterus. Douglas's sac is sutured to the uterine fundus posteriorly. supravaginal amputation of the neck of the uterus.

3. Posteriorly the sectioned vaginal mucosa is sutured to the posterior half of the stump of the neck in such a manner that a perfect adaptation is made between the vaginal and uterine mucosae.

In front the vaginal column previously isolated is deprived of its superficial mucosa and shortened at its free extremity so that there remains only a strip of solid submucous tissue which is sutured to the anterior edge of the sectioned neck. This submucous strip is then covered by the two quadrilateral flaps previously mentioned. The operation is completed by Lawson-Tait's colpoperineorrhaphy.

The advantages claimed for this operation are:

1. Consolidation of the musculo-aponeurotic ring which includes within it the isthmus of the uterus, and high fixation of the uterus in approximately its normal position.

2. Abolition of pathologic peritoneal formations constituted by the uterovesical and uterorectal sacs.

3. Reduction of the weight and volume of the uterus by amputation of the neck.

4. Narrowing of the lumen of the vaginal canal and of the vulvar orifice: cure of cystocele and rectocele and consolidation of the perineal floor.

5. Preservation of the integrity of sexual function.

The author reports eight cases very successfully treated according to this method and in at least one case it was followed by normal pregnancy and parturition.

W. A. BRIDGES

Hussey A. A. Operating During the Puerperium for Cure of Old Lacerations of the Cervix and Perineum. *Am J Obst Gyn* 1916 **xxix** 14.

The author reports 4 cases in which Stuart and himself had operated for cure of old lacerations of the cervix and perineum during the puerperium. He does not contend that this time of operating is more favorable than other times but thinks that for some of the poor patients in the maternity wards there may be some real gain by operating at this time, since so many of these patients will not return to the hospital even though they are more or less invalidated because of their lacerations.

In 29 of the cases operated upon the recent labor had been conducted under normal conditions in the delivery room. In two cases labor began outside the hospital and terminated in the receiving ward without preparation for delivery. One case was admitted with a transverse presentation with prolapse of the cord and arm after unsuccessful attempts at version by the family physician. Placenta previa complicated two cases. In two cases labor was induced with a bougie. Labor was terminated twice with podalic version and twice by forceps.

The lesions found in these cases were 3 old lacerations, 9 old and new lacerations of the perineum, 5 old lacerations, and 6 old and new lacerations of the cervix.

The cervical lacerations ranged from moderate single to deep multiple. The lacerations of the perineum were incomplete in 38 cases and complete in 2. One case was complicated by a cyst of Bartholin's gland and hemorrhoids.

The time selected for operation was from one to fifteen days post-partum. Five cases were operated upon twenty-four hours after delivery, four cases forty-eight hours after delivery. In 9 cases, the operation was done between the third and seventh days, and in 4 cases between the seventh and fifteenth days post-partum. The post-operative course was entirely normal in 35 of 40 cases and 5 had a little temperature.

In 25 of 29 cases of trachelorrhaphy the cervix is

recorded as healed. Partial union occurred in 3 cases and non-union in one.

Good union was secured in the perineum in 38 cases, and partial union in six cases, non-union is recorded in one case. The condition of the pelvic organs on discharge was normal in 34 cases, while retroversion of the uterus was noted in 6 cases.

The presence of lochia did not seem to have any unfavorable effect upon healing. The post-operative care did not differ from that of cases repaired after recent injuries.

C. H. DAVIS

Healy W. P. Sterility in the Female. *Mtd Rev* 1916, **lxxix** 954.

Sterility in the female may be due to pathological conditions grouped as follows: (1) malformations, (2) inflammations and infections, (3) injuries, and (4) tumors.

Relative sterility cases in the fourth group are due to fibroids of the uterus or in the third group there may be miscarriages as a result of uterine displacements or traumatic lesions of the pelvic organs following previous pregnancies.

The gonococcus is chiefly responsible for sterility due to inflammations. Practically all cases of absolute sterility belong etiologically in the first and second groups. Lack of complete development of the uterus is the most frequent factor in the first group. On this the clinical findings fall into three groups: (1) small poorly developed uterus with scanty menstruation, (2) small uterus with anteversion, a normal period, and dysmenorrhea, (3) a normal sized uterus with long conical cervix, stenosis of the cervical canal, menorrhagia, and dysmenorrhea. Any one of the above groups may be complicated by retroversion. Apparently normal organs in apparently healthy sterile women are found. These cases often have excessively acid vaginal secretion.

Apparently normal cases are benefited by saline douches at bed time and a restriction of intercourse. Groups 1 and 2 should have dilatation, curettage, and stem pessary. Group 3 can be helped by dilatation, curettage, and the Dudley operation on the cervix.

Retroversions should be corrected by pessaries or operation.

Sterility due to gonorrheal infection is least satisfactory to treat. Those cases in which no palpable lesions of the adnexa exist should have dilatation, curettage and saline douches. Failing this an exploratory laparotomy should be done with proper care of any adhesions found.

Gonorrheal cases with palpable lesions require curettage and plastic surgery on tubes.

W. F. HEWITT

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Costa R. Treatment of Extra uterine Pregnancy in the Advanced Periods (La terapia della gravidanza extrauterina nei periodi avanzati) *Gazzetta medica* Milano 1916 lxxviii, 29

The author believes that after the sixth month active intervention is necessary. If the fetus is dead operation can be delayed for about a week if the condition of the mother permits it. If the fetus is alive the termination of the pregnancy can be awaited.

Intervention can be made vaginally or abdominally. In the former the colpotomy incision must be sufficient to allow free passage of the head. Introduction of the hand or external maneuver are generally to be discountenanced and it is best to allow spontaneous placental climination.

Abdominal extraction is indicated only when the conditions are unfavorable for vaginal extraction. Median incision is the rule but when the sac is developed in the large ligament the Pfannenstiel incision is resorted to. Difficulties in abdominal extraction are ascribable not to the fetus but to the treatment of the annexes. These may be left intact or they may be partially or totally removed. The latter is the ideal way. In leaving the appendages behind there should be partial or complete closure of the abdomen. Partial closure finds its indications in septic or suspected cases when the sac and the placenta are firmly adherent or dangerously implanted on other organs, such as the liver, bile-ducts, etc. or when the placenta is very difficult to remove. In this case the technique is reduced to the opening of the abdomen and the sac, the extraction of the fetus tamponing marsupialization of the sac, and partial abdominal closure. Total removal of the ovarian tissues is the ideal procedure and the most correct surgical method.

W. A. BREXMAN

Arnold J. O. Some Practical Points in the Treatment of Eclampsia *Therap. Gaz.* 1916 4, 381

Arnold believes that a judicious combination of the Stroganoff or conservative method with some of the best of the more radical measures is in most cases productive of more satisfactory results than an attempt to follow either school alone. The Stroganoff method in several of the large European maternity hospitals has reduced the mortality in eclampsia from 20 per cent or more to 8 per cent or less. It is, consequently, the duty of obstetricians to give serious consideration to such a method and so far as possible to adopt it in practice for no other treatment has ever given half so low a death rate.

Most American and English obstetricians however believe that the uterus should be emptied whenever one or more convulsions have occurred. Consequently the author feels that after the convulsions have been controlled by the Stroganoff method it is logical to terminate pregnancy by whatever procedure will give the least shock to the patient.

Arnold's plan of treatment is in brief:

1 Chloroform if necessary in the smallest possible quantity that will enable one to give the first dose of morphine without disturbing the patient.

2 The first dose of morphine at least half a grain to be repeated in two hours or as soon and as often as is necessary to control the convulsions.

3 Bleeding as early in the attack as possible to the extent of from 12 to 24 ounces sufficient to effect lowering of the blood pressure.

4 After cleansing the lower bowel, the administration by rectal seepage of a solution containing 1 or 2 drams of sodium bromide and 2 or 3 drams of sodium carbonate to a quart of normal saline as rapidly and constantly as it may be absorbed. In case of rectal intolerance he advises a solution of 2 drams of bicarbonate of soda to the pint of normal saline by hypodermoclysis.

5 In cases before the eighth month after two or three convulsions induce labor. After the eighth month terminate pregnancy by the most appropriate method.

6 With the possible exception of water, no drugs or food are to be given by mouth until long after the convulsions have ceased.

The author reports 17 cases with a mortality of 5.

He states that in every case in which treatment was carried out efficiently from the start the results were good. Some of the consultation cases seen late were moribund and could not have been saved by any method of treatment. F. C. IRVING

Boyd G. M. The Indications for Caesarean Section *Am J Obst. N. Y.* 1916 lxxiii 650

The author believes that the low maternal mortality from caesarean section within recent years has led to an almost reckless broadening of the indications until at the present time this operation is performed far too frequently. He considers pelvic deformity in which the true conjugate is less than 7.5 cm. and pelvic obstruction as the only definite indications. As long as the etiology of eclampsia is obscure, its treatment by means of caesarean section is questionable. In rare cases he thinks it worthy of consideration but considers manual dilatation and rupture of the membranes, followed by

version or forceps, the better method of treatment for most cases. It is to be considered in some cases of placenta previa and is the method of greatest safety for central placenta previa. He questions certain so-called indications as face, brow occiput posterior positions, pyelitis, and primary inertia. He urges that the test of labor should be given the patient in all cases in which the indications are only relative.

C. H. D. via.

Costa, N. P. Segmental Cesarean Operation (Cesarea segmentaria). *Seminario med.*, 9 6 xxi, 55

Under this title are included those procedures which involve the lower segment in contradistinction to the classical cesarean operation which always involves the uterine body. The group includes supraumbilical inguinal, cervical posterior sections and laparocolpohysterotomy.

The author refers to the various procedures since Jorg of Leipzig in 1807 and Omander about the same time first exposed their technique. Ritgen put the extraperitoneal method into practice in 1821. Thomas, of New York in 1870 revived the technique of Ritgen and the statistics published later by him and his followers showed a maternal and fetal mortality of 50 and 42.8 per cent respectively which was no higher than the mortality from the classic operations.

In more recent times the methods were multiplied and according to Holzapfel and Franck there were in 1907 no less than seventeen distinct procedures. The author summarizes each of these methods which he states may be arranged in two great groups, the extraperitoneal and the transperitoneal. The first was founded on anatomical principles, the transperitoneal method arising as a necessity due more or less to the difficulties of technique which in the majority of cases sufficed to completely nullify the object of the intervention. Franck originally followed the extraperitoneal route but owing to the difficulties encountered was the first to try the transperitoneal and published his first seven cases in 1904. His procedure was later modified by Sellheim, Latzko and others.

Accidents are more numerous by the extraperitoneal route owing to the anatomical difficulties and conditions arising which cannot be foreseen. The most common accident is peritoneal injury and according to the statistics of Jeannin and Schauta the peritoneum was opened in about twenty per cent of the cases. Novvian's statistics showed 3.3 per cent, but Latzko and Doderlein by their procedure reduced the figure to 1.5 and 7 per cent respectively.

The next most frequent accident was vesical rupture which occurred in about 3 per cent of the cases. These and other lesser accidents are, however, reduced to a minimum by the transperitoneal method. Sometimes the terine muscle is lacerated or torn. As late accident fixation of the uterus to the abdominal cleftrix has been observed, and this facilitates retroflexion. Such adhesions, ac-

cording to Wiebel are met with in 25 per cent of the cases but they rarely cause a premature delivery or a grave dystocia.

The principal indication for a segmental cesarean operation is in a case where the classic operation is contra-indicated, i. e. a case with infection. This indication, however has not borne the brunt of criticism because the transperitoneal procedure with its provisory sutures is not capable of hindering contamination of the peritoneal cavity or preventing the evolution of fatal peritonitis.

Sellheim from his studies considered that segmental cesarean section was the only treatment in placenta previa and in six cases so treated by him and one by Henkel there were no deaths.

The general opinion however appears to be that this procedure cannot compare with pure obstetrical procedures with the classical cesarean section except in very special cases or in case of complete dystocia. Any other condition which contra-indicates the classic operation are indications for the segmental i. e., threatened rupture of the uterus or incomplete rupture of the lower segment pulmonary tuberculosis, meningitis, pelvic tumors etc.

The author believes that owing to the one hand to the great number of cases of subsequent rupture in the scar and the adherence of the uterus to the abdominal wall and organs in the classic cesarean, and on the other hand to the absence of such complications and more especially the firmness of the segmental cleftrix, this intervention should be studied further and an endeavor made to give it broader indications. Concerning the maternal and fetal mortality and morbidity the author refers to Jeannin's statistics, published in 1900, which gave 5 cases with a global mortality of 7.3 per cent. Eliminating eight deaths due to infection reduces the figure to 5.33 per cent. Latzko's statistics, omitting infective deaths, gave an operative mortality of 4 per cent, Novvian's 3.6 per cent. Bumm's 2.85 per cent. Wiebel's 3 per cent.

Jeannin's statistics showed more or less grave post-operative complications in about 30 per cent of cases. Novvian's 4 per cent. Fetal mortality varies according to the different statistics from 1.15 to 3.6 per cent including deaths prior to intervention. Asphyxiated births compare favorably with the classical operation.

According to the statistics the segmentary cesarean operation has an advantage of more than 50 per cent over the classical operation. Among the principal objections to the classical operation, as pointed out by Sellheim, are hemorrhage, intestinal laceration, difficulty of infection of abdominal cavity by the introduction of amniotic fluid and blood, epiploic adhesions, danger of electrical rupture in later labors, frequency of abdominal hernia, etc.

Schauta has pointed out that most of these are merely the result of faulty technique and thinks that segmental cesarean section lacks the advantages claimed for it and that the probability of infection is greater. Although opinions are divided the

author concludes that dominant opinion at present is for uncomplicated cases the classical operation for suspicious cases the segmentary and for manifestly infective cases a Porro or utero parietal tuba operation W A Bar

Beach R. M.: The Management of Ovarian Tumors Complicating Pregnancy Labor and the Puerperium. *Am J Obst & Gyn* 1911 viii 1029.

From the frequency of ovarian tumors and their infrequency as a complication of pregnancy the author reasons that these tumors do actually prevent conception. A thorough routine examination of all antepartum cases as early in pregnancy as possible will do much to eliminate the danger of the situation. Beach finds that the main complications of torsion, rupture and suppuration, occur in 5 to 30 per cent of the cases associated with the pregnant or puerperal state.

The author believes that ovarian tumors discovered during the first half of pregnancy should be removed by ovariectomy before the second half of pregnancy. If the tumor is discovered during the second half of pregnancy it should be removed if of considerable size since the excessive distention of the abdomen might tend to interrupt pregnancy. A waiting policy should, however, be chosen for other cases, such as dermoids, broad ligament tumors, pelvic bound tumors and bilateral tumors in the childless woman.

Non-obstructing tumors discovered during labor should not be operated upon if labor is progressing well. Obstetric manipulations should be limited and labor made as easy as possible.

Obstructive tumors seen during labor are considered under three headings: (1) Clean cases seen early in labor may be treated by posture and reposition, cesarean section plus ovariectomy or waiting until full dilatation of the cervix, which is dangerous owing to the possibility of rupturing the cyst. (2) Clean cases at the end of the first stage should be operated upon as that method gives the best insight into the condition present. (3) Infected cases seen late in labor must be operated upon at once. Cases that pass through labor should be operated upon during the puerperium.

C H Davis

Danforth W. C.: Pyelitis of Pregnancy with Especial Relation to Its Etiology. *S & G* 1911 96 xxii, 23.

The author made simple cultures on Flood's medium of the urine of 50 pregnant women. In only five of these were colon bacilli found. The remainder showed a growth of staphylococcus. A further series of 14 was much more carefully studied; the urines being cultured in agar plates to which human ascites fluid had been added in agar shake cultures and in anaerobic tubes of agar to which had been added human ascites fluid and goats blood. None of this series showed colon bacilli. One showed a

pseudodiphtheria bacillus, one an unrecognized spore-forming bacillus. With the exception of a few which were entirely sterile the remainder showed staphylococcus.

An observation is included upon a case in which the ureter was catheterized to relieve distention of the right kidney pelvis. The catheter would not pass up the right ureter although it passed up the left one readily. Upon placing the patient upon the left side to permit the ureter to gravitate away from the ureter the catheter passed up the ureter very readily and unimpeded rapidly from the catheter. It is assumed therefore that obstruction of a mechanical character can be caused by the ureter. As colon bacilli were so infrequently found the author assumes that the infection is in the majority of cases a blood-borne one.

As to treatment in addition to postural methods the use of the ureteral catheter is urged previous to distending upon emptying the uterus. The author believes that a considerable number of cases may be relieved by this means. Nephrotomy and nephrectomy are discussed.

Norris, C. G.: Pregnancy in the Tuberculous. *Am J Obst & Gyn* 1911 96 l viii 99.

The study of this subject has led the author to believe that as a general rule pregnancy and especially the puerperium exerts an unfavorable influence upon the course of tuberculosis. Whether the normal pregnant woman is more susceptible to infection by the tubercle bacilli is still an open question. It is certain that a definite proportion of women apparently contract the disease either during pregnancy or the puerperium. This is particularly true of the wives of tuberculous men living in an unhygienic surroundings.

The combined results of fourteen observers show that the average infant mortality in a large series of cases was 38.83 per cent. Armand Delille studied a series of 8 children born or living in 175 families, one or more members of which were tuberculous. Of these children 323 were placed in the country and did well, 306 even removed from their infectious surroundings and of these 235 developed tuberculous.

Apart from the exacerbation of the pulmonary condition which occurs so often during pregnancy, it seems that these patients are more subject to the various obstetrical complications than normal individuals.

Alberk of Norway treated 16 patients in a private sanitarium, yet 6 died within fifteen months. Lissen-Moeller reports that death or aggravation occurred in 50 per cent of his patients treated in private sanitariums. Ebeler from a study of 32 cases advises the immediate emptying of the uterus in any month of pregnancy. Barry reports that in a series of 38 cases all of the severe type, 50 per cent died within two months after labor. Bacon estimates that 33 per cent of tuberculous women die in less than one year after labor.

Practically all authorities recognize the gravity of laryngeal tuberculosis. Fellner in a series of 380 cases had a maternal mortality of 44 per cent. Lobenstein collected 23 cases of laryngeal tuberculosis from the literature 200 or 86 per cent of whom died during pregnancy, labor or soon after and Raspine emphasizes the ill effects of this condition. The death-rate among the infants of these patients was about 60 per cent. Imhofer reports a fetal mortality of from 86 to 90 per cent when the mother has a laryngeal involvement. Kneitner 90 per cent and several others give similar figures.

Tuberculous women should not nurse their children, except in exceptional circumstances, for the mother's sake and because of the dangers to the child.

Unfortunately despite the most painstaking studies, it cannot be determined with certainty which women will bear pregnancy and the puerperium well, and which will fare badly. The safest plan for the tuberculous woman is to avoid conception. In those exceptional cases in which conception has been countenanced, strict hygienic measures must be enforced and the woman kept under close observation and examined at frequent intervals by the experienced internist.

In the early months of pregnancy with a rapidly advancing pulmonary lesion, there can be no question but that the induction of abortion should be performed without loss of time and this is also true if laryngeal involvement occurs. On the other hand, given a similar case in the late months of pregnancy little can be gained by the induction of premature labor. The author believes that in the presence of an extensive lesion, even in the quiescent period or even of a small active lesion, or any laryngeal lesion the uterus should be emptied at once. The longer a lesion has been inactive the better the prognosis, as a general rule.

The combined statistics of 1 observer, comprising nearly 1,000 cases of intervention within the first four months indicate that 77 per cent of the women were benefited by emptying the uterus, the percent age varying from 20 to 97 per cent. The author believes that the wise obstetrician will familiarize himself with the results obtained by others, and that he will individualize his cases, and empty the uterus only when it is necessary but that he will not allow his natural repugnance to the performance of this operation to influence him to the detriment of his patient, if after consultation it seems advisable.

C. H. DAVIS.

Vantrien. The False Appendicitis of Pregnancy (Les fausses appendicites de la grossesse). *A. N. de gynéc. et obst.* p 6 xiii, 77

The author reports five cases in which there was a diagnosis of appendicitis, all the clinical signs apparently being precise and conclusive, but which proved wrong on intervention.

In the first case a gangrenous diverticulum showing all the symptoms of appendicitis called for urgent

operation. The appendix was found absolutely normal. In two other cases the trouble was found to be due to a suppurated dermoid ovarian cyst. The fourth case was very interesting. It presented all the classical signs of sudden pains in the right lower abdomen, particularly located over McBurney's point. Intervention, however, showed the cecum and appendix to be healthy with a hematic collection above them which extended into the iliac fossa as far as the uterine cornua behind and the broad ligament below. A disrupted impular pregnancy on the right tube was found coincident with a small uterine pregnancy which continued to term.

The fifth was a post partum case which was found to be due to the twisted pedicle of a partially suppurated ovarian cyst, the symptoms of which simulated appendicitis.

W. A. BRIDGEMAN.

LABOR AND ITS COMPLICATIONS

Grav, H. Fetal Dystocia and Cesarean Section *Med. Rec.* p 6 lxxix, 137

The author reviews the various forms of treatment of fetal dystocia with a plea for the more frequent performance of cesarean section for this complication.

The various forms of fetal dystocia are classified as follows:

Fetal dystocia from faulty attitude (1) excessive flexion of the head, Roderer's obliquity (2) Bregma presentation, incomplete flexion (3) brow presentation (4) face presentation (5) presentation of ant nor parietal bone or ear Naegele's obliquity (6) presentation of posterior parietal bone or ear Lutmann's obliquity.

2. Fetal dystocia from faulty presentation (1) pelvic presentation (2) shoulder presentation (3) fetal dystocia from faulty position (1) persistent occipitoposterior position (2) persistent mentoposterior position.

3. Fetal dystocia from general fetal conditions (1) multiple or compound presentation (2) multiple birth (3) malformation (4) deformities (5) anomalies.

5. Oversize of fetus.

6. Oversize of head.

7. Premature ossification of head.

8. Congenital hydrocephalus.

In many cases of delayed labor due to fetal dystocia haste is unnecessary, a quick and immature conclusion should be avoided. The history of the case must be fully considered whether the labor is at term or over due, the duration and progress of labor, the nature of the uterine contractions, especially as to the efficiency, the general condition of the mother, the condition of the amniotic sac, the condition of the fetus, and of the uterus and the condition of the rectum and bladder. Full information as to the above points will serve to assist in determining the proper procedure to follow. Having obtained a full history of the case a careful examination of the mother and fetus should be made.

Under full anaesthesia the whole hand if necessary should be passed into the vagina and an effort made to correct any faulty attitude or position and if possible to engage the head in the pelvis. By allowing labor to continue many faults will be spontaneously corrected by the forces of nature or rendered amenable to an easy forceps delivery.

Under operative treatment the author disregards embryotomy upon the living child, pubiotomy is not considered.

The high forceps operation is regarded as a dangerous procedure for both mother and baby and justifiable only under exceptional circumstances. The high fetal mortality and considerable maternal morbidity of version should cause it to be regarded as a formidable procedure.

For clean cases cesarean section is the ideal mode of delivery yet its dangers, shock, hemorrhage and sepsis must be weighed against the dangers and limitations of the alternative operations.

PHILIP F. WILLIAMS

Telfair J. H. Rupture of the Uterus During Labor
Am. J. Obst. & Gyn. 96: 133, 1955

The author gives a brief discussion of this subject reviewing some of the recent literature and showing that one of the more common causes working to increase this condition at the present time is the reckless use of pituitrin in the general practice of obstetrics. He reports two cases of rupture of the uterus during labor, the first occurring during the process of what was apparently a normal labor in a slightly poorly nourished woman and the second probably caused by using rather large doses of pituitrin in a case having a generally contracted pelvis. Following the rupture both cases were operated upon, one dying seven hours after operation and the other on the fourth day from peritonitis.

In the discussion of this paper a number of cases which have not been recorded in the literature on this subject were reported.

C. H. DAVIS.

Nicholson W. R. Anaesthesia in Labor. *Ther. & Gyn.* 1916: 388.

Nicholson estimates that about 15 per cent of normal women in normal labor really need anaesthesia, not merely to accomplish delivery successfully, but to do so without evil after effects. The remaining 85 per cent could probably be delivered as satisfactorily without anaesthesia as with it. With this in mind it behooves the obstetrician to select an anesthetic for use in labor which is not only efficacious but also safe for mother and child.

Chloroform is an efficacious anesthetic and easy to administer but its danger is great enough to preclude its use. Its margin of safety is narrow and its secondary results are frequently serious.

Ether is the safest of anesthetic agents. Its use as an analgesic has been quite satisfactory. It is cheap and easily administered.

The experience of those in this country having had a considerable experience with the scopolamine

morphine narcophan pantopon method varies from practically complete success to marked failure. At best it should only be used as an adjuvant to the first stage. As a means of procuring a painless delivery it is non-efficient and dangerous, the danger being due to the impossibility of individualizing the patients together with the uncertainty of the action of the drugs and also their relatively slow elimination.

Nitrous oxide and oxygen after one has had some experience in the use of the apparatus will be found 100 per cent efficient instead of failing in from 10 to 40 per cent of cases as does scopolamine. In the hands of a capable anesthetist nitrous oxide and oxygen is no more dangerous than ether. Its administration especially to the deeper surgical degree should not be attempted by one unskilled in its use. With this anesthetic there is no increased tendency to asphyxia neonatorum nor is labor prolonged nor is post partum bleeding increased over the normal.

F. C. LIVING

Ferreira F. Obstetrical Analgesia by Epidural Injections of Novocaine (La analgesia obstetrica por inyecciones de novocaina de novocaina). *Cron. Méd.* 96: 37.

Ferreira reports the details of five cases in which he made injections of novocaine solution combined with sodium bicarbonate and sodium chloride according to the method of Lowen as an obstetrical analgesic. The injections were made in the ligamentous membrane of the sacral region, and gave favorable results.

W. A. BRENNAN

Iraeta, D. Analgesias in Parturition (Los analgesicos en el parto). *Terap. Buenos Aires* 9: 6.

Morphine as well as other analgesic derivatives of opium given during labor may produce slight symptoms of intoxication but may cause the death of the fetus. As to the sensational discovery of Paulin of Paris that in obstetrics morphine can be separated from its toxic substances, without influencing its analgesic properties, the author accepts it with the suspicion of the existence of an oxytocic in the product injected, basing the suspicion upon the presence before the period of analgesia of a short period of hyperesthesia and a concomitant increase in the intensity of the uterine contractions.

The author in collaboration with Houssay and Beruti had succeeded in detoxicating morphine by the use of ferments. This product newly obtained was injected in different animals and it was demonstrated that the new product was of greater toxicity than morphine itself. Injecting in a series of parturient women a solution of ferments it was found that it had an oxytocic action more ephemeral than that of the hypophysis.

Clinical experimentation showed that major doses of 0.02 g. of morphine caused an increase in the intensity of the contractions immediately after the injection and that the pain decreased much sooner.

The author has devised an apparatus, inexpensive and easily manipulated, to register uterine contractions and to combine direct observation with external hysterography.

Internal hysterography must be abandoned in his opinion for the following reasons:

1. The balloon is difficult to place if there exists no relative dilatation of the cervix, and more difficult to place when the head has passed the perior strait.

2. During the expulsion period, the balloon is pushed out with the progress of the foetus.

3. The entire apparatus introduced into the uterine cavity is an excitator of the contractility of the organ and modifies its rhythm and intensity.

4. If the bag of waters is intact the balloon pushed in may break it and give rise to dystocia.

5. It is difficult to avoid displacing the balloon when it is in the uterus.

6. It is dangerous to the mother as well as to the foetus to introduce an apparatus into the uterus.

The difficulties encountered have resulted in the abandoning of this method.

The apparatus consists of the brassart of Pachon, moderate and a Marey's drum.

The brassart inflated and held by means of leather straps, is applied to the abdominal wall in the region of the fundus of the uterus at a point where it is not influenced much by the respiratory movements.

The rubber tube that starts from the brassart is placed in communication with a small Barnes bag, placed in an ordinary milk bottle, whose other tube opening is united by another rubber tube to Marey's drum. The author also uses an apparatus consisting of a drum, one face of which, flexible and provided with a spring, is put in contact with the abdominal wall by means of a spring the other rigid, holds a tube which communicates with a Marey's drum.

The registering cylinder used is one of the Bartsch type, of a voluntary regular movement. As the registrations indicate the time of the beginning and termination, one can easily calculate to any segment of the graphic, the duration, the intensity and the frequency of the contractions.

The objections which could be raised against this procedure may be due to the operator and the selection of the case. In the author's experience the apparatus gave only indications relative and comparable in the same subject and at the same session.

The high and low altitude of the register depends upon the degree of compression of the apparatus on the abdominal wall and it is very difficult to find it the same in different subjects.

The height of the tracing which corresponds to the intensity of contraction, is not represented on the graphic, because the air pressure in the drums increases with the progress of contraction, and, therefore during the last half of the contraction the resistance opposed would be much greater than at the beginning, consequently the height of the tracing will be lower than for the first half.

A question which arises is: Are the traces on the registering cylinder or graphic, the signs of uterine contractions only or are they the traces of contractions of the abdominal muscles also? The author states that the contraction of the abdominal muscles during the period of dilatation is a factor that disturbs the register very little because the corresponding muscles remain passive during the period of labor.

In an illustrative case a woman was chloroformed, and the apparatus applied; the registrations of the contractions were equal before and during the anesthesia.

The author's experiments upon women and animals led him to the following conclusions:

1. Morphine maintains the activity when mixed with hypophyseal solutions.

Internal hysterography must be discarded for it is dangerous to both mother and foetus.

3. In the study of uterine dynamics use should be made of external hysterography which is harmless.

4. A dose of morphine 0.005 g per gram of animal weight is fatal to guinea pigs.

5. Morphine is not detoxicated by hypophyseal solutions.

6. The leaves of grain or beer not only fail to detoxicate morphine but seem to increase its toxic effects in animals.

The physiological action of analgesin and pantoanalgesin according to the renal pressure and the uterus, is equal to that of morphine.

8. The combination of large doses of morphine to small doses of hypophysis annihilates the oxytocic action of the last named.

9. Solutions of leaves have less oxytocic action than those of the hypophysis.

10. The generalized opinion that pain and pregnancy are factors opposed to morphine intoxication is of no value.

Morphine injected in a pregnant woman may be transferred to the fetal circulation without changes.

1. The sensibility to the toxic action of morphine is greater in children.

3. The personal susceptibility to morphine varies greatly in different individuals.

4. In some parturients the initial dose of morphine does not relieve the pain instantly but it soon relieves the succeeding ones.

15. In 40 per cent of cases there is no indication for the administration of large doses of morphine for the relief of labor pains.

16. Products having morphine for a base, intended to produce analgesia in parturition are of inconstant action.

7. The injection of these products during the period of expulsion has little effect; their administration in obstetrical cases is not only unnecessary but injurious.

18. Opium derivatives do not relieve labor pains without changing the uterine dynamic, diminishing the number and intensity of the contractions.

19 Parturient women subjected to such analgesics suffer more or less from symptoms of morphine intoxication

20 Compounds with morphine as a base may in toxicate a parturient woman without decreasing labor pains.

21 Generally speaking the periods of dilatation and expulsion are prolonged in analgesized parturients

22 The duration of labor is approximately nine to ten hours for multiparae and twenty four hours for primiparae.

23 Artificial rupture of the membranes must very frequently be performed in analgesized women

24 Analgesics increase the necessity for obstetrical intervention.

25 Opium derivatives used as analgesics in parturition intoxicate the fetus in about 38 per cent of cases

26 The administration of morphine compounds to a parturient woman may cause the death of the fetus.

27 Chloroform by the drop method may be used as a harmless analgesic and should be used in preference to all other anodynes

28 The administration of chloroform in surgical doses produces serious disorders in the uterine dynamics

RAOUL L. VIGORIN

Olivella, R. and Arteaga, I F Parto-Analgesia (La partonalgia) *Rev Méd d S Illa* 9: 11 99.

In 7 reported cases the author has used the preparation recommended and used by Cantón de Buenos Aires as a parto-analgesic. This preparation is composed of

Chlorhydrate of morphine 4 centigrams

Hypophysis extract (fresh gland) 10 centigrams

Sterile vehicle 1 cubic centimeter

The author found that in all cases pain was diminished notably and in fact was not appreciable except at the passage of the head that the contractions persist that the parto-analgesic produces marked somnolence that the digestive, circulatory, respiratory and urinary apparatus were not affected that post partum vomiting occurred in only one case that involution was normal that the child in only one case was born asphyctic and in this case recourse was had to artificial respiration that the infants during the first twenty four hours were unperfected and dull and required watching

W. A. BRENNAN

PUERPERIUM AND ITS COMPLICATIONS

D Lee J B: Puerperal Infection *Chc g M Recorder* 9: 6 11 34

The statistics of 1914 show that 3 500 women died in the United States from puerperal infection that 10 women per day died in the United States from puerperal infection during that year. This is the reported number from the 66 per cent of the reg-

istered population of the United States which means that the deaths are reported and are received at the Census Bureau at Washington. In addition to those dying from puerperal infection there are a large number of women who die under an entirely different diagnosis

It is generally considered that puerperal infection is due to an infection of the parturient canal by germs and probably that is true. It is believed that the streptococcus causes most of these infections. Probably that is true too but other germs likewise cause puerperal infection such as the staphylococcus (three kinds) the gas bacillus in rare cases and in rare instances the diphtheria bacillus. How these infections get in however and why one woman is infected by a bacterium that leaves another woman intact we do not know

One factor that has a great deal to do with the incidence of infection is the epidemic influence. At certain seasons of the year the bacteria that are ordinarily present in the room and in the dust and air acquire the highest degree of virulence

The conduct of labor has as much to do with the prevention of infection as the asepsis of labor. To put it in a nut shell the asepsis of the labor the sterilization of gloves and hands and all implements the handpiece the mouthpiece that go with the proper aseptic conduct of labor are not all there is to be done in the prevention of puerperal infection. To this must be added the proper conduct of labor

Considering all cases of puerperal infection at the start because that is the time when local treatment if it does any good at all should be instituted we can make the sweeping declaration that the local treatment of puerperal infection has seen its day. There is still a rather marked difference on one point regarding local treatment. There are those who believe that if the physician is convinced there is decomposing material particularly placental in the uterus it should be removed at once. If a woman has an undoubted puerperal infection and has a piece of placenta in the uterus the greatest danger she runs is the danger of hemorrhage and it has been the authors practice wherever hemorrhage did not exist to leave the piece of placenta in the uterus until the protective barrier which Nature throws up against the advancement of the infection has been thoroughly established and enables the uterus to be invaded without the danger of spreading the infection. However if hemorrhage interferes with this expectant treatment something has to be done and there is the choice of two remedies one tamponing the uterus and stopping hemorrhage that way hoping when the tampon is removed that the piece of placenta will come with it and the other is immediate manual digital rarely instrumental removal of the piece of placenta. That such a course of treatment is successful and is not dangerous has been proven time and again and has been proven by the respectable minority of men who believe in that form of treatment. The protective wall of granulation should not be disturbed

If a piece of placenta in the uterus is infected and is causing puerperal infection, by the time the woman has had the first chill the bacteria are far beyond the uterine wall. They have gone into the blood into the connective tissue, if they are going at all.

If a woman has a hemolytic streptococcus in the uterus, whatever is done to the uterus helps very little because the infection has gone beyond the reach of anything that can be done locally. If also has not a streptococcus hemolytic infection, it makes little difference what is done, because the infection is superficial and in the course of time will be cast off by itself but one should avoid doing any thing which would convert a non-virulent invasive organism into a virulent and invasive one. The question is asked: Would not a piece of placenta decomposing in the uterus in itself conduce to the development of invasive qualities of a hitherto non-invasive and harmless organism. This question? has been answered Yes and No. It has been said that the streptococcus living as a parasite is harmless in the genital tract, but given enough placental tissue and blood to feed on, it will develop invasive qualities, and by removing the pabulum the streptococcus will not develop these qualities. This has not been proven by experience. It has been shown time and again that if a wound that is granulating nicely in which Nature is throwing off infection in a successful way is opened and the granulations broken down, a veritable inoculation of the woman with bacteria is produced.

The other methods of treatment: vaginal douches, while not very harmful, are not entirely harmless; they do no good and had better not be given. Brushing the uterus with tincture of iodine the author discontinued long ago but one form of local treatment he still insists on and that is the removal of perineal and cervical stitches. He believes in providing free drainage. If there is plenty of room for the secretions to get out, then there is a greater chance of overcoming the infection. Outside of the removal of the stitches the author uses no local treatment.

In the general treatment he still uses antistreptococcus serum. If a patient comes down with chill, high temperature prostration, and presents the symptoms of streptococcal infection he gives 500 ccm. of the serum. If she does not make a marked improvement, he discontinues the treatment. The author has not seen any complications arise from pains in the joints and urticarial eruptions.

DeLee uses very few vaccines because he has seen no benefit from them. Neither has he seen much, if any beneficial effect from collargol and electrargol. Normal salt solution is a good diuretic but he has not had the wonderful results from it that his colleagues report.

The author's advice is: Do not be in a hurry to open a pelvic abscess. Of course, that does not mean you will sit by and let it break into the bowel or the general peritoneal cavity or break out on the skin. Do not be in a hurry to take out a pus tube

after puerperal infection. He has never taken out the uterus for puerperal infection, and he notes that there is great conservatism manifested in the operation of removal of the uterus.

In the prevention of puerperal infection he lays particular stress on the method of conducting labors in the hospital: also the chances of infection being spread after sterile supplies are exposed to the air.

EDWARD L. CORDELL.

Hedblom, C. A. A Case of Phlebitis Migrans. *J. Am. M. Ass.* 9 6 1917, 777

A married woman of 26 was in her fourth pregnancy in five years. The first two babies had died of marasmus the third was living and well.

The labor progressed without incident and a 7.25 pound baby was born at the end of the twelfth hour by normal mechanism. No laceration of the perineum occurred. The placenta came away after ten contractions. The uterus was atonic and in spite of ergot and massage there was rather more than the average amount of bleeding, but the pulse did not go above 90.

The temperature remained between 99 and 100.5 for the first ten days of an otherwise uneventful convalescence. On the seventh day the patient had a drenching night sweat and there was a sharp rise of temperature to 104 pulse 120. The breasts were normal the fundus well down and not tender. The white count was 17,000 haemoglobin 60 per cent. There was marked tenderness and some induration over the course of the right saphenous vein, and the leg soon became swollen and oedematous. Treatment consisted in elevation, use of the ice bath absolute rest etc. After three days there was marked drop in temperature and pulse, and, although the tenderness and swelling extended progressively down to the foot, there was a gradual but steady improvement until the beginning of the fourth week. At this time the temperature again rose sharply to 104.5° pulse 135 and marked tenderness, induration, and swelling developed in the right thigh. The patient was nauseated a great deal during the next two weeks, vomited at intervals, and complained of pain in the epigastrium much aggravated by food. The pulse remained about 130, became weak and irregular and there was increasing prostration in spite of the fact that the swelling and tenderness in the legs all but disappeared.

During the sixth week of illness these symptoms recurred first in the left and then in the right leg with pain in both legs and feet which became so severe as to prevent sleep, except after morphine. There followed, however, a period of general improvement during which the patient was again able to take food, and for several days the pulse and temperature remained at about normal. During the eighth week induration, tenderness, and swelling appeared progressively over the left side of the neck, axilla, arm, and left chest. There was also increased swelling in the left flank and lower abdom-

mal wall which was spastic and very tender to palpation. The swelling in both legs increased and pain in the legs and feet became so severe as again to require the administration of morphine. The temperature was from 102 to 103, the pulse from 130 to 140 and at times almost imperceptible. During this recrudescence which lasted about two weeks gangrene developed over the anterior aspect of both feet which resulted finally in the separation of the whole thickness of the skin and partial sloughing of the tendon-sheaths.

After another interval of improvement there was a fourth relapse during which the right side of the neck, the right axilla and arm became involved and then successively the occiput, whole scalp and face. During the height of this attack sharp pain developed in the chest aggravated by deep respiration but no friction rub or other signs were elicited. There were nausea and vomiting lasting several days. The voice became husky and the patient complained of severe headache and pain in all affected parts but most marked in the feet. The symptoms abated toward the end of the tenth week for a period of about twelve days. This was followed by the sixth and last relapse characterized by abrupt rise of temperature from normal to 102, the pulse was accelerated from 120 to 140 and again became irregular and at times almost imperceptible. At the beginning of this attack there was a good deal of vomiting and violent headaches. The swelling in the neck and scalp which had begun to subside also increased. After four days the patient became erythrovous, suffered lapses in memory and finally became partially irrational for several days. Ophthalmoscopic examination, papillitis of both optic nerves, outline of both disks entirely lost, vision almost normal but with duplication of objects.

The patient was discharged in the nineteenth week in good general condition. Nine months after the onset of the illness there was no swelling or disability the patient was in excellent health and of maximum weight and was able to play golf and tennis. She was admitted two months after this time and an appendectomy done for subacute appendicitis.

MISCELLANEOUS

Commisskey L. J. J. Routine Wassermann Reaction in Hospital Obstetrics. *Am J Obst* 1919, 66, 1391-1406.

This report is based on the routine Wassermann tests in 1822 mothers and 1004 newborn infants, the larger number of mothers being due to the fact that the women were subjected to the test eleven months earlier than the infants as a routine and also that some mothers left the institution undelivered. Of the mothers tested 145 or 8 per cent were

positive 26 or 14 per cent were doubtful and 11 negative or 0.6 per cent had infants whose reactions were positive or doubtful. Only 6 or 18 per cent of these women with positive reports gave any history or showed any signs of syphilis leaving 119 or 52 per cent with positive reports who showed neither clinical evidence nor gave a history of the disease. From this it can be seen that many cases would have escaped diagnosis but for the routine Wassermann reaction. The conclusions are as follows:

1. The routine Wassermann reaction is the ideal method for the detection of syphilis in the pregnant woman or as near the ideal as our present knowledge will permit.

From this comparatively small number of cases it would seem that syphilis has but a slight influence on the length of gestation but does seem to produce a much higher percentage of stillborn infants.

That the use of the blood serum from the umbilical cord for the treatment of others is unwise and dangerous, without the Wassermann being done upon both the fetal and maternal bloods.

4. That the death rate among children of Wassermann positive mothers is four times greater during the first ten days of life than in the case of children where both mother and child are negative.

C. H. Davis.

Iyer H. N. A Case of Siamese Twins. *I J* 1919, 11, 3.

The author reports a case of a woman aged 26 VI para who had been in labor for three days. Upon her arrival he found a fetal head and left forearm delivered. These had been exposed for six hours. On vaginal examination a second head, with its face turned toward that of the delivered one, was found. Attempts to push this head into the uterus failed. With some difficulty forceps were applied to the undelivered head with gratifying results. A common placenta was delivered shortly.

The twins were found to be attached by the rib cartilage. They were lying on their sides facing each other and the left hand of one was between the heads. The heads were distinct and all facial organs well formed. There were four hands, four legs, two separate vertebral columns and a common abdomen covered only by pentoneum. There were two separate pelvic bones and male organs. A single cord passed under the pentoneal covering of the abdomen. The small and large intestines were found occupying both portions of the abdominal cavity. There was a single liver and spleen. There were two pairs of kidneys, a single heart, two lungs and a common diaphragm. A case of Siamese twins — both stillborns.

GENITO-URINARY SURGERY

ADRENAL, KIDNEY AND URETER

D. VILLA, S. A Case of Malignant Tumor of the Right Kidney in a Child of Four Years (Sopra un caso di tumore maligno del rene destro in un bambino di 4 anni) *Riv di cl. pediat.* 9 6 xiv 69

Malignant tumors of the kidney which are frequent are fairly familiar in pediatric literature. During the past years in the pediatric clinic of the University of Rome, 14 such cases have been observed.

The first impression given by the case reported by DeVila in a girl of 4 years was that of an echinococcus cyst of the liver. The differential signs, however, ruled this out as well as other possible tumors, and the ultimate diagnosis of tumor of the right kidney was arrived at and intervention decided upon.

Under chloroform an incision was made in the cecal region and the cecal peritoneum opened up. On clearing away the pericecal tissues and adhesions the tumor was found. The adhesions were between the anterior face of the tumor, the abdominal wall, and the colon. Luxating the tumor through the wound it was found to be attached to the right kidney by a pedicle. With its appendages the tumor weighed early 800 grams.

Histological examination showed that the tumor consisted wholly of sarcomatous, partly myxomatous connective tissue, except at its inferior pole, where there was a zone of integral renal substance. In the lower pole was also found a urinary cyst and some small hemorrhagic cysts. The tumor was composed mainly of fibrous fascia and young fibroblasts. This is the usual finding in histologic examination of malignant tumors of the kidney in children.

The subsequent operative history of the child shows that except for a bronchopneumonia there were no complications and five months later there was no evidence of recurrence.

The author gives a summary of the previous cases which are recorded in the clinic. The general mortality of non-operated cases is 100 per cent. In the operated cases the operative deaths averaged 40 per cent, deaths by recurrence after operation, 45 per cent, definite recoveries, 7 per cent.

W. A. BRIDGMAN

FRASER, A. The Origin of Hypernephroma of the Kidney *Surg. Gynec. & Obst.* 9 6 xiii, 645

Of 34 so-called hypernephromata studied by the author on was almost undoubtedly a neoplasm originating in an accessory nest of cortical adrenal cells, and

the patient who was a woman, aged 38, was 6 feet in height of excellently developed musculature, the hair on the head, the chest, arms, and legs was thick, coarse and abundant and there was a distinct mustache. The mammae were undeveloped and the chest was of the male type.

In 3 of Fraser's cases of so-called hypernephromata the morphological evidence indicated that the tumors were derived from the tubules of renal adenomata and had no histogenetic connection with the adrenal cortex. For this reason he suggests that the term hypernephroma be used only to include tumors which are undoubtedly of cortical adrenal origin, and that the term neophrimata be applied to that large group of renal tumors to which the designation of hypernephroma is now given. In support of this opinion he points out that the primary structure of adrenal tumors is essentially different from that of tumors of renal origin, that the primary structure of adrenal tumors never imitates that of renal tumors, but that the primary structure of certain renal adenomata can at an early stage through pathological changes imitate the primary structure of tumors of renal origin. Both tumors of renal and of adrenal origin are capable of undergoing secondary degenerative and malignant changes rendering their histological features almost identical.

KRIEG, A. Abscess of the Kidney Cortex and Its Relation to Paranephritic Suppuration (Ueber den Abscess der Nierenrinde und seine Beziehung zur paranephritischen Eiterung) *Beitr. z. Klin. Chir.* 9 6 xxi, 44.

The patient in the case reported by Krieg was a girl of 5. The history showed influenza and frequent neck inflammation. The present disease began suddenly with pains in the right lower abdominal segment, high fever, tendency to vomit, etc. Appendicitis was diagnosed and laparotomy done. The appendix was found to be normal. On the under pole of the right kidney a cherry-sized tough growth was felt. On freeing the kidney this was found to be a cortical abscess. About 30 abscesses from the size of a pin to that of a pea were found scattered on the surface of the kidney. The kidney was extirpated and recovery has persisted for the two years since the operation.

The author thinks that the observations are of importance with regard to unilateral kidney abscesses, in that the case throws light on the method of development of such abscesses. If of hematogenous origin, the cortical abscesses had directly attacked the fibrous capsule and involved the neighboring tissue. By this means the way was opened to the fatty capsule and it is seen that the developed

paranephritic abscess condition had its origin in the cortical abscess

W. A. BROWN

Wilk Surgical Treatment of Nephritis

gutsche Behandlung der Nephritis
A. med. Woch. Nr. 1, 1900

Wilk reports on four cases of nephritis in wounded soldiers in which medical treatment was of no avail, but in which surgical intervention gave excellent results.

In each of the four cases decapsulation of the kidney was done under local anesthesia supported by etherization during isolation of the kidney. After operation the renal activity began to increase in all four cases.

In these cases the author thinks it is not a question of anatomopathological alteration of the kidney but rather a functional disturbance, a promising and diminution of the renal activity due to tuberculin and compression by adhesions of connective tissue which envelop it and which has passed into the cicatricial state after inflammation.

Decapsulation is clearly indicated in such cases and if this procedure in the case of the second kidney should be operated upon.

W. A. BROWN

Kretschmer H. L. and Gaarde F. W. The Treatment of Chronic Colon Bacillus Pelletis by Pelvic Lavage

25

The authors refer to the already published results as to the possible dividing line between pyelitis and pyonephrosis with abscess formation and chyma. General treatment is not sufficient and the results from lavage. The greater the number of suitable cases and the results of the treatment were. The authors have tried the treatment in 15 cases. Cultures obtained from the kidney had to be sterile.

As a rule the growth of the colon bacillus was easy to obtain on plain agar although in some cases it was necessary to try the blood agar. In all the kidney had cleared up this emphasizing the bacteriostatic action as to the lymphatic channels. All four elsewhere. It will never be a cure. One per cent silver nitrate was the main method employed in a case of chronic pyelitis. The treatment was resorted to every three days. Various manipulative treatment as well as various were resorted to. Of 14 cases 4 were cured. Logic cases were observed in 11 instances. From one to eight injections were required. The authors believe that this treatment is more certain and speedy than any other advised and that failure signifies the same such complication in fact as stone or tuberculous.

F. R. CHARLTON

Gilpatrick, R. H. Nephropexy

B. J. M. S.

This author presents a critical review of the most operative procedures for permanent nephropexy in which because resulting in the normal renal function should be discarded. Nephropexy as a curative agent in many cases has resulted in failure because too much was done in operation which does not and cannot cure the disease proper growth but a mechanical defect. This must be a mechanical defect in position or function. It is dependent upon strict adherence to principles of physiology which sling basket and mechanical operations which restrict the kidney.

The author proceeds to discuss the various methods of fixing the kidney through the abdominal wall at the lower border of the rib cage. The capsule is used from the pole of the kidney to the organ. The pole of the capsule is then turned back and three sutures are passed through each by an incision in the abdominal wall. A generous amount of pulp is drawn up in these sutures. The pole of the capsule is then turned back and three sutures are passed through each by an incision in the abdominal wall. The kidney is then placed in position and the sutures are brought out through the incision. The wound is then closed. The uppermost sutures are brought out. When all sutures are tied the position of the kidney is accurately approximated. The position of the quadratus lumborum and the area of incision are marked upon the uppermost must average at least four quires. The muscular edges of the incision are sutured with uterine suture. The kidney is sutured with uterine suture. The operation is completed by closing the incision and the uppermost sutures.

Ten cases have been operated upon according to this technique with successful kidney-embarrassment. The average stay in the hospital is 14 days. All wounds healed by first intention. All patients reported freedom from symptom present before operation.

The author offers the following conclusions:

1. A mechanical problem is better solved under good mechanical principles.
2. Success is dependent upon the degree to which normal anatomical and physiological conditions are approached.
3. The kidney may be wounded fixed or constricted with impunity.
4. Decapsulation is either partial or complete does not impair kidney function.
5. The most rational method of securing the kidney in position after it has become a wandering

to such a degree as to demand operation is that of removing the cause and aiding in the reconstruction of a natural support.

6 Any permanent artificial support is dangerous if not completely destructive to the kidney's functional activity.

7 The rolled-up and transfixed capsular flap offers a perfectly adequate hold for one end of the anchorage and the muscular and fascial layers of the loin the same for the other end, without sutures which emerge through the skin.

8 If the anatomical relations of the kidney can not be permanently readjusted without destruction of its functional activity it should be either left alone or removed.

M. KROGSAVED

Pedersen V. C. A Seven-Glass Urinary Test
V. Y. M. J. 9, 6, cli, 867

The necessity of a clinical means of recognizing prostatic disease apart from seminal vesicular disease and of vesicular disease of one side apart from that of the opposite side, and likewise of the prostate indicated Pedersen to evolve the procedure described. He does not claim that it is absolutely accurate but says that it will furnish the clinical basis of operation very satisfactorily by demonstrating whether the pus is chiefly or solely in the prostate as distinguished from the vesicles or vice versa, or in one vesicle independently of its fellow or of the prostate gland.

The author dwells upon the anatomy of the organs in question, and shows with the aid of illustrations how this test can be logically carried out. It performs this test by two methods, the one-stage and the two-stage. The patient's bladder should be reasonably full of urine or should be filled at the time with normal salt solution. For each specimen 100 to 150 ccm. of urine are necessary.

In the one-stage method Glass 1 is obtained by irrigating the anterior urethra as far back as the cut-off muscle before urination. The wash water will show the amount of involvement of this portion of the urethra.

2 Glass 2 which he calls the anterior urethral control glass, is obtained in the same manner and its contents are from the same source. While obtaining Glass 1 it is advisable to massage the urethra upon the catheter in order to express the contents of any infected urethral follicles.

3. Glass 3 is obtained by having the patient pass about 50 ccm. of bladder urine. If the bladder is normal this glass will contain almost solely the contents of the posterior urethra, whose nature will be shown by the microscope as the products of posterior urethritis in uncomplicated cases, or of this lesion combined with drainage product from the prostate and vesicles in complicated cases.

4. Glass 4 obtained by cautious catheterization with a different catheter from that used in the irrigation of the anterior urethra, will show with a microscope that there is no pyuria, or that if present its origin is either vesical or renal.

5. Glass 5 is called the poststatic glass to obtain which there must be considerable urine left in the bladder or that organ must be distended with normal salt solution. The prostate is then massaged solely along the lateral borders of the lateral lobes where they form a distinct sulcus for the finger in the rectum between the prostate medially and the fascia of the pelvis outside it. Great care must be taken to avoid the middle of the prostate along the urethra where the course of the ejaculatory duct lies. After this massage the patient passes 150 ccm. of bladder content and this presents prostatic secretion normal or pathological foramina.

6 Glass 6 is the first seminal vesicle glass designated in accordance with the side from which it was taken. The author prefers to elect the vesicle which seems to be the least diseased on the ground that its contents may be far more normal, and he always begins with the normal vesicle if its fellow seems solitary in involvement. After massage of this organ, the patient must evacuate another 15 ccm., which will contain so purely the products of the diseased vesicle as to make the specimen of great clinical value.

7 Glass 7 or the second seminal vesicle glass, is obtained in similar manner by massage of the remaining seminal vesicle. In sterility the seven-glass test carried out in the usual manner will show whether or not both testicles are involved and whether or not there is atrophy of the two seminal vesicles.

The two-stage method consists in carrying the examination through Glass 6 in the ordinary way just described, and then postponing Glass 7 until a subsequent visit. The urine which at the first sitting was not massaged is now evacuated and the patient empties his bladder into one or two glasses, according to the call for a control specimen. This detail is extremely valuable where tuberculosis is suspected, and the contents of one vesicle must be carefully separated from those of its fellow.

The author illustrates the value of the seven-glass test with a chart of specimens obtained from numerous cases, and he also gives several case reports.

In conclusion, Pedersen says that this test is not infallible and no such claim is made, but no test possesses the quality of infallibility. It is not self-sufficient and the author does not so state but few tests are really self-sufficient not even the X-ray which commonly requires corroboration or is itself only corroborative. The seven glass test requires, first of all, digital skill in massage as such, and then with the parts of the prostate and seminal vesicles which are to be reached and with those part of the same organs which are to be voided during the massage which this test demands. It will be well for the beginner to study many patients personally before being satisfied with his own skill in the manipulation, and therefore convinced of his own deductions from the test. J. D. BARRY

Cameron D F: Variations in Renal Function
Dependent on Surgical Procedures *J Am
Med Ass* 19 6 1917 705

Cameron's work shows that in surgical diseases of the urinary tract the phenolsulphonphthal in test and the blood urea test are practically parallel although there is one type of case in which the phenolsulphonphthalin excretion is diminished but the blood urea is normal. He also shows that the relief of any type of urinary obstruction results markedly the percentage of phenolsulphonphthalin excretion accompanied by a drop in the blood urea. The most interesting portion of the article is the result of the determination of blood urea after operation with nitrous oxide-oxygen anaesthesia with rebreathing. These patients all show a decrease of the blood urea some of them just high. After operations under ether anaesthesia the increase in the blood urea if any was much less. Hence this small series of cases would fail to support the contention that nitrous oxide-oxygen ether anaesthesia has a less deleterious effect on renal efficiency than has a pure ether anaesthesia.

The author summarizes his results as follows:
The agreement between phenolsulphonphthalin and blood urea tests is as a rule very striking though not infrequently a low phenolsulphonphthalin excretion is associated with an unusually moderately increased blood urea concentration.
These tests are of great importance in selecting the most opportune time for operation so far as renal function is concerned.

Following an operation under a general anaesthetic there is, as a rule, an increase in blood urea concentration. This increase is most marked after operations on the urinary tract and especially on patients who already have diminished renal function. In a small series of cases the increase was slightly more marked following operations under gas oxygen-ether anaesthesia than following similar operations under ether.

Blood urea determinations are of great value in the diagnosis and prognosis of uremia. Not infrequently blood urea concentration can be determined when other renal function tests are very difficult or impossible to use.

In this investigation definite symptoms of uremia in uncomplicated cases appeared when the blood urea concentration reached 180 to 200.

There is a definite group of patients who have a low phenolsulphonphthalin excretion but a normal or approximately normal blood urea concentration. Many members of this group withstand a general anaesthetic without any complications due to renal insufficiency.

V D LLEVIN, MD

Pedersen V C: The Diagnosis of Ureteral Calculus
J Am Med Ass 19 6 1917 709

This method is not intended as a modification for or as a substitute of that described by Burton Harris but rather as an application of it to the Brown Buerger cystoscope. The method of preparing the

wax tip itself and the compound of wax and the same as those detailed by Harris likewise the technique of passing the wax tipped filiform into and coiling it within the bladder full of urine or of boric acid water artificially introduced. The sheath of the Brown Buerger instrument has a very well fitted trum which when passed along the filiform guide in the urethra chafes and even causes smart hemorrhage from the distal urethra in many cases. In order to avoid this the author has devised an obturator having a well fitted at the vesicel end and at the handle of the sheath through which the filiform guide is threaded. The obturator protects the mucosa and permits easy introduction of the instrument without pain or bleeding. The distending fluid in the bladder escapes through the slots of the obturator. The thin thickening telescope is passed through the distal urethra and the wax tip brought into view exactly as Harris describes rotated completely under the eye for demonstration of any scratch and then passed into the ureter. The author leaves the filiform again to the tone after rubbing it upon it and then withdraws the cystoscope and the filiform as one instrument. The distance from the eye piece to the wax tip is almost the exact distance of the stone from the mouth of the ureter. This method will be found direct simple and accurate and in adapting the Harris method to the Brown Buerger instrument the use of a Nitze instrument is unnecessary for which instrument Harris originally described his technique.

BLADDER, URETHRA, AND PENIS

Legueu F: Extraction of Bullets from the Bladder
by the Natural Route (Le trait par les
voies naturelles des balles de l'essai) *J d'rol*
9 6 1895

Fragments of shell or shrapnel balls on account of their irregular form and sometimes their large caliber must always be removed from the bladder by the operative method.

Rifle bullets on the contrary being smooth and of a sufficiently small caliber can be removed through the urethra. Legueu has thus removed all such bullets which he has found and considers it the method of choice.

To carry out this procedure it is necessary that the bullet be quite within the bladder free movable and have no concretions. Radiography in two different positions will generally determine some of these conditions but cystoscopy must be relied on. It alone shows without error the presence the situation and the mobility of the bullet and it alone can show all the conditions which it is necessary to know before proceeding to extraction.

Legueu's procedure is very simple. He uses No. 00 lithotrite which he has adapted for this purpose, and by touch alone performs the extraction. The instrument is introduced into the bladder by the urethra in the usual way just as if a stone were to be removed only that the bullet must be seized

either by the point or by the base, and not transversely. The dimensions of the urethra easily permit extraction. No anesthetic is necessary unless the bladder is extremely sensitive or the patient cannot stand the proceeding. W. A. BRENNAN

Turner, G. G. Foreign Bodies in the Bladder Resulting from Gunshot Wounds. *Lancet* Lond. 9 6 Dec, 1918.

The author cites three cases of wounded soldiers in the present European War in which the foreign body had presumably lodged in the bladder at the time of the casualty. In each instance there was some urinary trouble from the outset. The lodgment of a missile in the bladder is an event well recognized in all campaigns. In most museums there are specimens of calculi in which the nucleus is formed by some type of bullet. In the X-ray investigation of such cases plates should be made with the patient in various positions and with the bladder empty and distended. Marked alteration in the position of the shadow will then be a guide as to the freedom of the foreign body in the viscus. A routine cystoscopic examination ought also to be carried out, for there may be some non-metallic foreign body in addition to that shown by the X-rays, or the foreign body may be entirely non-metallic, and a negative X-ray examination is therefore not enough to establish the diagnosis.

It is interesting to observe how the wound in the bladder spontaneously closes. Small foreign bodies always tend to escape with the urine but those that cannot negotiate the urethra may sometimes be safely removed in the eye by an evacuating catheter. Leguen, using a specially modified lithotrite, has removed rifle and machine-gun bullets per urethram rapidly and without general anesthesia. For shrapnel bullets, large or ragged fragments of shell, or incriminated foreign bodies the author considers the suprapubic route the method of choice, and he believes it will certainly be the safest in the hands of those without special training. H. A. MOORE

Saviozzani, V. Treatment of Gunshot Wounds of the Bladder (Contributo alla terapia delle ferite d'arma da fuoco della vescica). *Clin. chir.* 9 6 Nov, 1918.

Saviozzani reports two cases of gunshot injuries of the bladder treated by suprapubic cystostomy and tamponade of the bladder opening with favorable result. In one of the cases there was found located in the bladder a bullet as well as some spiculae from the fractured innominate bone.

Gunshot wounds of the bladder are more frequent than any other kind of bladder wounds. Bartels collected 85 such cases but it is only very rarely that as in one of these cases, a bony fragment is carried into the bladder by the projectile. Bladder injuries of this kind are classed either as intra-extraperitoneal. In the intraperitoneal variety the prognosis according to most writers is absolutely

fatal. Although this prognostic conception seems rather exaggerated to the author yet in the statistics of 5 cases, collected by Rivington, of intraperitoneal cases there was no recovery nor was there a recovery in any of the cases reported by Bartels.

Extraperitoneal injuries have, however, a more favorable prognosis, but it is difficult to determine whether the injury is intra or extraperitoneal as the early symptoms in both are identical.

Regarding treatment the prime necessity is to arrest hemorrhage and assure the flow of urine. Some recommend the *sonde à demeure* in extraperitoneal injuries, others recommend suture of the bladder and laparotomy in either variety of injury.

As to the treatment adopted by the author, i. e., cystostomy with tamponade of the bladder (with laparotomy also in the first case) he thinks that the brilliant result obtained authorizes him to strongly recommend this procedure because it is rapid, safe, and in serious cases can even be carried out under local anesthesia. In these cases suture of the bladder was technically impossible and in gunshot wounds accompanied by a perivascular hemorrhage the difficulties of suturing are such as to favor the simpler and equally safe method adopted by him.

W. A. BRENNAN

Davis, E. G. Vesical Drainage: Historical Review and Presentation of a New Apparatus. *J. Am. M. A.* 9 6 1919, 680.

The author reviews the various forms of apparatus used for urinary drainage following suprapubic cystostomy. The ideal apparatus permits urinary leakage from the time of operation until the patient is healed requires little attention causes no inconvenience to the patient and is simple and inexpensive.

The author describes and illustrates the apparatus used in the James Buchanan Brady Urological Institute. Two bottles of 8- and 16-liter capacity rest on a stool on the floor beside the bed. The larger one is a vacuum, which is gradually decreased in strength by leakage of air through a minute capillary glass tube from the smaller bottle. When the smaller bottle the air pressure is slightly less than one atmosphere so that by virtue of this difference the urine is drawn out of the bladder through a catheter and tube into the smaller bottle. As the urine drops into this bottle, it replaces the air which has leaked into the vacuum of the larger bottle. The capillary tube is placed within the vacuum bottle to keep the apparatus as compact as possible.

The air pressure within the urine bottle is regulated by a small U-shaped manometer of glass tubing with a lumen of 3 mm. For the sake of convenience and safety this manometer is also placed inside the vacuum bottle. In the bend of this tube is a small amount of mercury which if sufficient pressure is exerted, will permit air to pass in either direction. This furnishes a safety valve which prevents the

pressure within the urine bottle from lifting from the atmospheric pressure by more than 20 mm. of mercury and also prevents the catheter from exerting more than the gentlest suction within the bladder.

The care of the apparatus is very simple. The urine bottle must be emptied when full and the air in the larger bottle exhausted at least every forty-eight hours. W. E. L.

Erkes, F. Manual Expression of the Bladder in a Spinal Injury. (Zur med. u. n. t. p. e. J. Blase bei Rueckenmarksläsionen. M. d. med. Wch. 18. 1910. 1. 5.)

In the case reported by Erkes there was a penetrating injury by a gunshot which traversed the spinal column. The entrance was at the fifth lumbar line and the outlet a little to the right of the spinal apophysis of the tenth lumbar vertebra. There was complete loss of sensation and motion in both lower limbs as well as bladder and rectal paralysis. To avoid catheterization the author practiced manual expression of the bladder through the abdominal wall which by this method is completely evacuated.

Laminectomy was done with extraction of the osseous fragments which compressed the dura mater. Later in the day the patient suddenly developed grave abdominal symptoms and died with symptoms of bladder rupture. At autopsy an ulcero-perforation of the fundus of the bladder was found.

The author thinks that manual expression of the bladder should only be made when there is no evidence of cystitis or any alteration of the vesical walls but that when this can be assured the method is capable of giving good results in selected cases. W. A. BREWER

Thomas, B. A. Total Cystectomy One and a Half Years After Operation. (Ibid. 1911. 1. 754.)

Thomas reports the case of a man of 41 in whom he found cystoscopically as the cause of excreting bladder-symptoms multiple variably sized small polypoid tumor formation completely covering the trigonum and vesical neck. Since various conservative operative measures including suprapubic incision, fulguration, suprapubic cystotomy with cauterization of the entire trigonum and vesical orifice had proved inadequate against the rapidly reforming polypi bilateral nephrectomy supplemented by total cystectomy eight months later was performed. A remarkably quick convalescence ensued. Four months later on account of recurrence of pain in the perineum and urethra suggestive of involvement of the prostatic urethra a radical perineal extracapsular prostatectomy and posterior urethrectomy were performed supplemented by deep implantation of 0.5 mg. of radium in the perineum for 48 hours.

The retrolumbar fistulae were fitted with silastic silver tubes connected with rubber tubing to a flat receptacle suspended over the suprapubic

region. The patient at present enjoys good health and has no difficulty in keeping himself dry.

The case reported by the author marks the first instance in which Watson's procedure suggested ten years ago was successfully accomplished alluring at the same time the practicability of the method as a satisfactory renal drainage apparatus. M. K. ROSENER.

Loumeau. Congenital Stricture of the Urethra. (Sem. t. n. é. de l'ur. 1912. 1. 134.)

Loumeau reports the details of three additional personal cases of congenital stricture of the urethra. The striking total number of case of this condition which has been considered rare reported personally by Loumeau within the last few years to twenty. W. A. BREWER

Shoemaker, G. E. Primary Carcinoma of the Urethra Retention of Urine from Obstruction Restoration of Function by Radium. (Ibid. 1913. 1. 13.)

The urethra has been called the rarest location for primary carcinoma. Most cases are merely extensions. In 1905 M. Murphy could find only 26 personal cases. Sielmann reports a case relieved by X-ray. Legeu and Chéron of Paris arrested the destructive process for two and a half years with radium.

In the author's case a multipara of 30 years applied because of complete urinary retention from urethral obstruction. There was no bleeding nor ulceration and no tumor. The urethra felt through the vagina like a hard fixed pencil-sized ridge extending from the retracted meatus backward nearly to the base of the bladder. The edges of the meatus were hard irregular nodular and ridge-like with but little enlargement or surrounding infiltration. As incontinence would have followed surgical removal radium was applied by the author in collaboration with Newcomet while bladder paralysis and cystitis from enormous distention were treated. After nine interurethral applications three hours each the patient was able to urinate normally. The urethra was still cordlike. Microscopical diagnosis quamous epithelioma. Wassermann test for syphilis was negative.

Rochet. Total Ischiopubic Disconnection of Deep Perineal Fascia in Order to Reach the Deep Urethra and Exteriorize the Prostatovesical Region. (Développement de la région périnéale et de la région prostatico-urétrale. L. 1910. 1. 134.)

Rochet refers to the varying procedures which surgeons have resorted to in order to find a relatively easy mode of access by the perineal route to the deep male genito-urinary organs. Young's perineal operation Boeckel's areolar operation of Folle's coccyperineal route as well as others are reviewed.

The author however finds all these methods limited and in seeking a method for reaching the deep perineal organs and bringing them completely out of the excavation has realized it by a massive mobilization of the whole deep perineum by lateral disconnection of the deep perineal fascia and its complete peripheral detachment from all the osseous ischio-subpubic triangle.

The operation is done in four stages. In the first the penis and scrotum being tightly drawn up a reversed V-perineal incision is made. The summit of the V corresponds to the subpubic angle and the sides of the V follow the ischio-pubic branches. This is practically Young's incision.

The second stage consists in the stripping of the deep urethra from the rectum as in an ordinary prostatectomy penetration into the recto-urethral triangle, section of the recto-urethral muscle, and separation of the anterior face of the rectum from the posterior face of the prostate.

In the third stage the membranous urethra is cut through immediately behind the bulb immediately before the deep perineal fascia. The anterior end of the urethra is slightly loosened up including the bulb and drawn away so as not to mask the field of operation.

The fourth part of the operation consists in an attack on the lateral attachments of the deep perineal fascia and on the deep perineum as far as the internal edge of ischium. This part of the procedure gives complete access and freedom of action on the prostate and lower portion of the bladder.

The author has carried out this operation in two cases of cancer of the prostate and he thinks the operation is indicated in cases requiring extirpation of the cancerous prostate, also when the lower part of the bladder is attacked by localized neoplasms. The high route of approach in such cases is difficult and the field is far from the reach of the finger and instruments.

W. A. BRENNAN

Thomas, B. A., Sitter, E. H., and Randall, A. Amputation of Penis for Carcinoma; Conditions Four and One-Half Years After Operation. *J. N. Surg. Phila.*, 9 6, 1911, 735

The case is reported of a man of 53 who in October 1901 had been operated upon for a typical carcinoma of the glans penis, involving the urethra, with metastasis to the inguinal lymph-glands on both sides and amputation of the penis close to the pubic arch.

Interesting features of the case are: Absence of recurrence, although complete extirpation of the penis with perineal urethrotomy was not done, and good functional result (ability to urinate in standing posture).

M. KROSTENKOV

GENITAL ORGANS

Gibbon J. H. The Treatment of Undescended Testicle. *Proc. M. J. Soc. 61st, 609.*

Because incomplete descent of the testicle is usually associated with a patulous condition of the

vaginal process, as in twenty-four of the author's twenty-seven cases, the congenital type of inguinal hernia, if not already present, is likely to develop. The undescended testicle is ever as large as the one that descends normally but contrary to the prevalent belief it is no more prone to malignant change.

An incompletely descended testicle in an infant can be drawn much lower down by regular daily efforts of an intelligent mother or nurse. The Boyan operation can be done at three or four years and by careful dissection the testicle almost invariably can be placed in the scrotum, but if not it should be returned to the abdomen rather than be excised.

The incision is the same as for hernia operation. The vaginal process is opened and divided transversely just above the testicle, the upper portion being treated as hernial sac and the lower portion is sutured round the testicle as a tunic. The lower portion of the sac is carefully separated from the surrounding structures and the spermatic cord is freely mobilized. This usually permits the testicle to be placed in the scrotum without tension but occasionally it may be necessary to ligate and divide the spermatic veins and artery. Owing to the free anastomosis between the spermatic artery and the artery of the vas, ligation of the former does not interfere with the circulation in the testicle. A pouch is next made in the scrotum by blunt dissection with the finger and the testicle with its tunica is placed therein. Retention sutures are not necessary except for a purse string which is loosely tied about the opening in the pouch. The inguinal canal is closed over the cord as in the Ferguson operation for hernia. In operations there were no deaths, no serious infections, and no post-operative disturbances of the testicle. In all 7 cases recently cured the testicle is painless, movable and in the position in which it was placed at operation.

J. B. CANNETT

Lavy. Treatment of Gunshot Wounds of Testicle (Zur Behandlung der Hodenverletzungen). *M. Wochenschr. u. B. u. Woch.* 9 6, 1911, 33

Testicular war wounds like other wounds of war are generally infected and with the patient under an anesthetic, the wound should be cleaned, washed and treated as an open wound. Infection is carried very easily into the serous cavity, but the most frequent and most serious complication in this class of injury is infection of the vaginal sac.

Lavy cites two cases one of which was due to mine explosion entailing lesions of both testicles treated with favorable outcome, following the technique recommended by Ritter, which consists in opening up the wound with a bistoury if necessary followed by lavage of the vaginal tissue, and suturing of the serous cavity.

W. A. BRENNAN

Raymond and H. Paratyphoid Orchitis Epididymitis (Orchitis-epididymitis paratyphoidique). *Bull. et mem. Soc. med. d. hop. d. Par.* 9 6, 1911, 551

The author gives the clinical details of a case in which there was a total disappearance of the right

testicle a small indurated stump alone remaining which appeared rather more epididymal than testicular.

Observations of such cases are still too few to give data for a clinical picture. However, in presence of the facts that are known it can be said contrary to the general opinion that these genital complications are far from being rare and that they are grave in general because they evolve with a tendency to suppuration and by destructive action cause testicular elimination. W. A. BRENNAN.

Del Valle, D. A New Operation for the Treatment of Varicocele. *Surg. (Ct.) Obst. Gyn.* 1914, 734.

The operations for the treatment of varicocele are numerous but none of them have fulfilled all that is required. Del Valle considers the following operation simple and the results better than those obtained by similar procedures.

1. Make an incision 5 cm. long on the external abdominal ring exposing to view the ring with its cord.

2. Dissect the anterior group of veins separating it from the other elements of the cord. It is not necessary to dissect the spermatic artery. In all varicoceles it is generally the anterior groups of veins forming part of the cord that is affected besides anatomically the anterior group has a greater number of veins and is more important than the posterior group.

3. Divide the anterior group into two subgroups anterior and posterior. Place a catgut ligature on the posterior subgroup one finger's breadth above the testicle and a silk ligature on the anterior one two fingers' breadth above the former on holding the thread.

4. Make an incision on the fascia of the external oblique within and parallel to the internal pillar of the inguinal canal introduce a forceps through the incision, directing it so as to come out at the orifice of the external abdominal ring seize the ends of the silk thread and pull through. Thus the entire anterior group of veins passes through the opening in the fascia and by means of a stitch it is fixed to it after ascertaining that the testicle has remained at the required height.

5. When the posterior group of veins is the one affected the operation is the same except that the opening in the fascia is made outside the external pillar of the inguinal canal and not within the internal pillar.

Louveau. Secondary Calculi of the Vesicoprostatic Region in Old Prostatitis (Les calculs de la région vésico-prostatique chez les anciens prostatitiques). *J. d. m. d. Bordeaux* 1916, txxvii, 35.

Where Frey's operation has been correctly executed there is often the ulterior appearance of calculi in the vesicoprostatic region owing to the existence above the prostate of an enormous cavity

into which the alkaline urinary salts are precipitated. The condition is not imputable to the surgeon but is a definite result of the prostatectomy.

Louveau thinks that prostatectomy should be followed up by disinfection of the bladder as long as the urine is not completely limpid and that the diverticular pocket of urining successive to prostatectomy should be suppressed by a perineal resection as this pocket is capable of permitting the formation of secondary and even primary calculi in situ.

In two cases in which Louveau observed secondary calculi subsequent to transvesical prostatectomy three times they were clearly attributable to post-operative prostatic cavities chargeable to the operation alone. W. A. BRENNAN.

Peterlin G. S. Calcareous Degeneration of the Prostate Gland. *Ann. Surg. Phila.* 1916, lxxiii, 68.

The patient 9 years of age sustained two trauma to the urethra by falls followed by copious purulent discharge from the urethra and symptoms of cystitis which continued for thirteen years, when a progressive enlargement and hardness were noted in the prostatic area. Palpation per rectum revealed a round smooth stony hard mass, the size of a medium sized orange. Cystoscopy showed general cystitis trabecular cavity with tenacious pus. The prostatic urethra showed phosphatic masses. The skilgraph revealed a large calcareous mass in the prostatic area which was removed through a suprapubic cystotomy. The mass weighed 31 grams. Ten days following operation the patient died suddenly from secondary hemorrhage. Autopsy was refused. I. S. KOLL.

Morton H. H. Suprapubic Prostatectomy. *Med. Times* 1916, xli, 150.

Morton describes two hypertrophic prostatic cases one 73 years old on whom a prostatectomy was done the other 84 years old upon whom suprapubic cystotomy was done for drainage as preparatory treatment for prostatectomy.

The first patient had led a catheter life for two years. This condition Morton designates as the third stage of hypertrophied prostates. Renal function tests had shown favorable results. Rectal examination demonstrated that the enlargement was high up in the pelvis and for this reason the suprapubic route was chosen. Hagner's bag was used to control hemorrhage instead of gauze packing formerly used by the author. Frey's drainage tube was now supplanted by one one-fourth its size in order to guard against a post-operative fistula. A lesser intake catheter was used occupying a considerable lower level than the outflow tube. A through and through silver wire suture was used in closing the wound.

The cystotomy case was done under stovain spinal anesthesia. Outcome of a bladder hemo-

rhage five years ago the patient had been free from trouble until the past few days when difficult urination occurred. For forty-eight hours retention was present, necessitating catheterization. Rectal examination found a middle lobe enlargement. A catheter was fixed in the bladder and continuous drainage allowed after a few days of gradual emptyings. However, the continuous drainage became faulty the patient slightly and toxicemic. On this account spinal anesthesia was selected instead of ether. Cystotomy was done and a jack-stone calculus removed. The prostate will be removed after the drainage has prepared the patient to withstand a prostatectomy.

Morton considers a low specific gravity (this case 1.015) with albumin, pus, and blood as prohibitive from either ether or even gas and oxygen anesthesia. He also considers cocaine unsatisfactory. Spinal anesthesia with atovaine 0.03 lactic acid 0.05 bolus alcohol 0.5 distilled water 9.95 cm is his preference.

The author cautions that the patient be slightly inverted after the spinal injection in order to keep the atovaine which is lighter in specific gravity than spinal fluid from leaving the lumbosacral region and thus prevent death from paralysis of the respiratory centers.

C. E. BAKER

Perrier, C. Transurethral Prostatectomy Under Local Anesthesia (La prostatectomie transurétrale sous anesthésie locale) *J d'ur* 9 6 vi, 509

Perrier reviews the various attempts which have been made to carry out prostatectomy under local or regional anesthesia. He points out that in most of these the method has necessarily to be more or less supplemented by a general anesthetic.

The author's method is a combination of these procedures which he avers has given him full satisfaction as typified in the five cases he reports. In detail the combined method is as follows:

1. Anesthesia of the bdominovesical wall by infiltration of 0.5 cc. of 1% adrenalin solution 1:200 the quantity used varying according to the stoutness of the subject.

2. Anesthesia by infiltration with the same solution of the bi-ischiatric line. This will allow of deep painless injections.

3. The left index-finger being introduced into the rectum, injection is made with long needles (10 to 15 cm.) under the prostatic capsule. According as the liquid is injected the capsule is felt to rise and extend.

4. Injection with similar needles of the sacral nerves with a solution 1:100.

Perrier is of the opinion that his cases show not only the harmlessness of the procedure but the pos-

sibility of applying it in cases which are most difficult from a technical point of view i.e. with very obese subjects where the prostate can only be exposed with much difficulty. Sloughing of the edges of the wound, as noted by Legueu has never been observed. In conclusion he thinks that a prostatectomy can be performed under local anesthesia with the same facility as a hernia or gall bladder operation.

W. A. BRENNAN

MISCELLANEOUS

Lydston, G. F. Sex-Gland Implantation *J Am M A* 9 1 540

The author gives an exhaustive summary of his previously published experimental work in sex-gland implantations with material taken from dead bodies and reports four additional cases of successful testicle implantations. In each case transplantation was made of the scrotum, testicle alone or of testis and epididymis from dead human bodies. One patient aged 45 has dementia precox and after the first operation also decided improvement. Another patient aged 29 a double implantation was done because of bilateral complete atrophy of the testes with restoration of virility and improvement in physical and mental vigor.

The author believes that the sex-gland hormone is the most powerful cell stimulant, nutrient and regenerative known to medical science and that sex-gland implantation preserves hormone production for prolonged periods. There is good reason to believe that physiologic and therapeutic advantages may be permanent. In none of the cases thus far observed has the implanted gland disappeared prior to twelve or eighteen months. The implantation may be repeated.

J. B. C. SMITH

Loumeau, Diabetes and Prostatectomy (Diabète et prostatectomie) *J d'ur* 9 6 vii, 35

Loumeau relates the case of a prostatic of over 70 who for the past three or four years had shown glycosuria which at the time of the examination amounted to 60 grams in twenty-four hours.

A two-stage prostatectomy was done with most excellent results and was followed by restoration of sexual and physical functions. In this case the diabetes which was of rheumatic origin had a permanent result on the prostatectomy which as a matter of fact cured the glycosuria.

Loumeau therefore thinks that contrary to the general opinion diabetes except in very severe forms is not an operative contra-indication.

W. A. BRENNAN

SURGERY OF THE EYE AND EAR

EYE

Stevens, H. W. The Clinical Significance of Radiographs of the Orbital Region. *Am. J. Roent. & Elect. Diag.* p. 106 v. 411

The author endeavors to show the value of making radiograms of the head in atypical positions. He especially presents positions to show the orbital region citing four cases in which the diagnosis could not have been made either by the stereoscopic lateral or anteroposterior plates.

Before using these new positions in attempting diagnosis he carried out a number of experiments in which he placed a metal object over the various lines of the anterior fossa and also covered some of the projections with lead foil. In this way he demonstrated that the interpretations by Rhese of certain markings were incorrect.

Owing to the asymmetry of the individual skull and the wide variation in the skulls of different individuals it is impossible to lay down a particular or definite procedure. Each case calls for a slightly different position of the skull on the plate. The author emphasizes the value of taking radiographs of both sides of the individual skull for comparison.

The usual position in obtaining plates for the proper study of the orbital region as stated by the author is as follows: The plate is so adjusted to the face that one edge rests upon the zygoma of the side under examination and the other upon the ridge of the nose.

The conditions demonstrated by this method of examination were as follows:

In the first case a lymphosarcoma of the orbit the change demonstrated by the plate was an increase in the size of the nasura orbitalis.

In the second case a new growth had caused the absorption of the crista galli and lamina cribrosa a condition which could not be demonstrated by the usual lateral plate.

In the third case there was a fracture of the floor of the anterior fossa, and finally a hemorrhage into the orbit.

W. A. EVANS.

Bourgeois, H. Twelve Observations of Orbital and Peri-orbital Fistulae (Douze observations de fistules orbitaires et péri-orbitaires). *P. S. Méd.* 916 xlii 5

The author reports on twelve cases of fistulae in the orbital region of which several were consecutive to war injuries. These were accompanied by lesions of the adneural cavities of the nasal fossae and sinuses. In the presence of such a fistula a tertiary fistulized ostium must always be thought of. Foreign bodies of small dimension or even small osseous fragments

suffice to cause these suppurations. Large opening must be instituted and the offending body searched out by the finger aiding the eye.

The ostium will be cured only when the healthy osseous tissue is reached. It is not less important to effect osseous reparation while avoiding secondary infection. This is best effected by leaving the osseous wound alone and suturing the operative wound as early as possible allowing only sufficient opening for drainage.

W. A. BERNARD.

Rhodes, G. B. Pulsating Exophthalmos. *Ann. N. Y. Acad. Sci.* 1961 389

In 1906 de Schweinitz and Holloway reviewed the reported cases of pulsating exophthalmos prior to that time. Since then the author has been able to collect 52 cases from the literature and to these he adds one of his own.

From a study of this series of 53 cases it appears that 3 of them were of traumatic origin and occurred spontaneously while in the cause was not given. In the traumatic cases there was usually a latent period of about 21 days before the first symptom the bruit appeared. The average age of the patients was thirty-six. Exophthalmos occurred at later periods varying from a few days to a month after the appearance of the bruit. Pulsation is a later symptom usually appearing within a few days after the exophthalmos has been noticed. Loss of the pupillary reflex with persistent dilatation of the pupil occurred in many cases due to the laceration of the carotid plexus of the sympathetic. Almost all cases showed an increase in the ocular tension but only two developed an absolute glaucoma. Diplopia, hemorrhages or edema of the retina, tortuosity and dilatation of the retinal veins were encountered with great frequency. Certain nerve lesions such as optic nerve atrophy, paralysis of the motor mechanism of the eyeball due to laceration or pressure on the individual nerves were commonly noted.

In these 53 cases practically all known procedures were employed with the exception of electrocoagulation. The author has given an outline of each of these cases with the operation and result and from them and the other cases previously reported in the literature it seems that ligation of the common carotid is by far the safest operation. In cases in which this fails one should be guided by the condition of the optic nerve as to further operative procedures. As cures have resulted after long periods if the nerve is not entirely gone and seems to be that it ended the orbital operation commonly known as Sattler's in which the superior ophthalmic vein is ligated should be attempted. This operation

while yielding good results, exposes the patient to the danger from hemorrhage in some cases.

I the author a case, ligation of the common carotid was followed by a complete cure, although the exophthalmos disappeared very slowly and was noticeable for more than four months after the operation. GATKHOON.

EAR

Read J S. The Necessity for Early Diagnosis and Continuous Treatment in Congenital Syphilis. *A. Ch. Polist.* 9 6 xxxiii 44.

The author concludes that the majority of these congenital cases are not receiving the full benefit of modern methods of diagnosis and therapy. The children of parents known to have or to have had syphilis should be considered to be until proved otherwise. If on clinical signs are apparent blood examination should be regularly made. If there is a suspicion of a taint in the child and the serum is negative the parents should be Wassermannized, and if tests are negative the child should be treated and again tested for often after a small amount of treatment a positive reaction will appear. If there is in the parents any history of chancres many years back, a provocative injection of salvarsan or mercury should be given and often a negative serum will read positive at the next test.

The author draws attention to the various symptoms which in an unsuspected case should arrest the attention and call for a differential diagnosis excluding the presence of syphilis: marasmus in a breast-fed baby showing no signs of indigestion; extensive peeling of the palms and soles a few weeks after birth; ouychia; a thinning of the eye brows in an infant a few months old; alopecia and any eye lesions in the very young; an unexplainable nephritis; a peroxymal hemoglobinuria; a hard swollen testicle occurring under one year of age; epiphyseitis within the first three months.

As to treatment, the same persistently selected application of salvarsan, mercury, K. I. and tonics are recommended as in adults, and the treatment should not be discontinued as soon as symptoms disappear but the course should be guided by clinical signs, serologic and other tests. OTTO M. ROTT.

Combes, G. M., and Erner, M. S. Vaccin Treatment of Chronic Suppurative Otitis Media. *Penn. M. J.* 9 6 xiv, 585.

The authors of this paper discuss the vaccine treatment of chronic running ears and report the results of a series of 50 cases treated with utoge-

nous vaccines of their own preparation, the results of complement fixation tests in 10 of the cases.

Wassermann reactions, and 15 von Pirquet's. All of the 50 cases observed were inveterately chronic in type. The result obtained was 46 per cent of dry ears up to the time of writing the paper, which was several months after the last case had become dry. Great stress is laid upon the technique of culture taking for vaccine preparation and place made for close co-operation between the clinic and laboratory. The technique used was to cleanse the middle ear and canal as thoroughly as possible with cotton swabs or by suction, fill the canal with alcohol for ten minutes, remove and dry by evaporation for fifteen minutes. Then by inflation or by suction, a drop of pus was obtained on a sterile platinum loop inserted through sterile speculum. Sometimes no growth was obtained evidently from too complete sterilization.

The authors believe that vaccine therapy will permanently stop the discharge in a good many of these chronic cases. Those showing much bony necrosis, especially in the mastoid, cholesteatoma and possibly labyrinth suppuration would probably not yield good results. They advise neglecting nothing in the way of local treatment of the ear, nose, and throat that may be indicated but that vaccine should be given in connection with all other accepted methods of treatment.

The reasons for failure to obtain dry ears are suggested as follows: (1) Failure to obtain causative organism. (2) Necessary continued inoculation. (3) Spontaneous recovery. (4) Course of preparation. (5) Incorrect dosage. (6) Possibly low antigenic powers of the organism and the contra-indications mentioned above.

A solution of the question of determining the causative organism was attempted and complement fixations done, all of which negative result was obtained. The antigens used were polyvalent strains of several of the ordinary pus-producing micro-organisms. In these same cases Wassermanns were all negative and of 5 von Pirquet's, 3 were faintly positive and 4 strongly positive without local evidence of tuberculosis in the ear.

In regard to complement fixations, the authors conclude either that (1) it is possible that only a few free amoebocytes are circulating in the blood in these cases. (2) Bacteria in discharging ears are too thick to stimulate antibody production. (3) A lowered body vitality may antagonize response to infection. (4) The reaction may be so well walled off that absorption cannot take place. (5) The technique used may not have been delicate enough.

SURGERY OF THE NOSE, THROAT AND MOUTH

NOSE

Dean L. W.: *The Control of Haemorrhage in More Extensive Operations on the Nose and Jaws*
Laryngoscope 19 6 xvi 9 3

Before performing a major operation about the nose, throat and jaws the author usually ligatures one or more vessels in the neck, then early in the operation the smaller peripheral vessels are seized with hemostats. Usually some time later in the operation it is necessary to use pressure with water etc. to control hemorrhage by seepage.

In removing a superior maxilla, half an inch where it is necessary to invade the palatal or tonsillar region, the author advises the performance of a tracheotomy and packing the pharynx, the tube being removed just as the operation is completed. An abundance of hot water and a large electric cautery should always be at hand for the control of deep hemorrhage and for seepage.

The most essential condition in the control of hemorrhage in major operations is to have a corps of assistants who have been associated with the operator in numerous operations so that everything for the control of hemorrhage is done promptly and with precision.

The author has had no experience with the ligation of the large vessels on the side of the neck. The ligation on one side has, with the exception of one case, proved satisfactory. (1911) M. R. R.

Thomson S.: *Malignant Disease of the Nose or Accessory Sinuses. Advantages of Operating Through the Face.* *Lancet* 1906 98.

The author makes a plea for the performance of the Moure operation or lateral rhinotomy for malignant tumors originating in the antrunasal wall, the roof of the nose, in the antrum or in the sphenoid. The advantages claimed for this procedure are:

1. In all cases there is no mutilation or disfigurement.
2. Patients will readily consent to the operation.
3. They are left with an intact roof to the mouth and no troublesome obturator is required as in the old operation of excision of the upper jaw.
4. It is much easier after a Moure operation to keep a direct lookout in the nose and its accessory cavities for any suspicion of recurrence.
5. Recurrences are more easily dealt with either through the nasal orifice or by repeating the lateral rhinotomy, and patients are less likely to object to this than to a further facial disfigurement.
6. It can be extended to meet the special conditions met with or may be combined with other operative steps, for instance if it is found that the

dissemination has deeply invaded the orbit this cavity can be cleared out through the same incision, preserving the lower eyelid, sacrificing the eye if necessary. The nasal septum can be removed if the growth has attacked it. The antrum might be further cleared out by an incision through the canine fossa, but the access to the antrum obtained by a Moure operation cannot be improved upon. This may also be combined with the Denker operation. If the floor of the nose is found to be invaded the addition of a Rouge operation can be made.

Externally the scar within a few months is so slight as to be almost invisible.

8. Hemorrhage can be well controlled.

9. The front wall of the sphenoid is brought so well into the field that it is hardly one inch from the surface.

The author describes the technique of the operation and reports two cases in which the Moure operation was performed.

In the first case, endothelioma of the ethmoid and antrum, there was no recurrence after five and one half years.

In the second case, epithelioma of the left maxillary antrum, there was no recurrence after three and one half years.

These cases demonstrated the following facts:

1. Both an endothelioma and a carcinoma in the nasal area are susceptible of satisfactory treatment by this method.

2. A history of some standing or exteriorization of the growth does not necessarily invalidate the good results.

3. Dangerous difficult and disfiguring operations which were formerly tried can be superseded by modern methods which in the hands of experts are easier, safer, cause no disfigurement and promise a lasting cure. (1911) M. R. R.

Veasey C. A.: *The Diagnosis and Treatment of Inflammatory Affections of the Nasal Accessory Sinuses.* *J. Ophth. & Oto-Laryng.* 1906 9 6.

After alluding to the importance of sinus disease as a causative factor in many gastro-intestinal affections, as well as toxæmias affecting other portions of the body, the author considers the sinuses collectively and mentions the well known symptoms of headache, tenderness, nasal obstruction and discharge, dizziness and vertigo, as well as apoplexia and neuroathenic symptoms in general.

As to diagnostic methods, the author mentions transillumination as one of the best methods of assisting in the diagnosis. Other aids, as the pharyngoscope, X-ray picture and irrigating tube, are

trum, and the application of sucll to the nose are favorably commented upon.

As to treatment of the acute condition, the author mentions the necessity of securing adequate drainage and ventilation, and this is secured by shrinking the nasal mucosa by the application of a weak solution of cocaine. Instead of adrenalin, as the latter is apt to produce secondary swollen condition greater than was previously present. After the membrane has been shrunk the author cleanses it with a normal salt solution with mild alkaline solution followed by an application of a 5 per cent solution of argyrol and an oil spray. The patient is instructed to douche his nose freely with hot normal saline solution every hour or two and to take deep inhalations every two or three hours of compound tincture of benzoin and menthol four ounces of the former and one drachm of the latter of which two tablespoonfuls are employed in one-half pint of boiling water. General treatment with calomel, saline, aspirin, and phenacetin is recommended.

The indication for the treatment of the chronic cases is likewise, drainage, whether obtained by the correction of obstructing septal deformities or hypertrophied turbinates. After drainage has been obtained irrigations are advised, and when these prove futile, operative interference is justified. Not much faith is held by the author in the beneficial influence of autogenous vaccines. Otto M. Rott

Berry J M. Radiography in the Diagnosis of Diseases of the Accessory Nasal Sinuses.
Arch. Radiol. & Electrol. 9 6 1914.

In radiographing the sinuses of the head the author makes use of the following positions: (1) postero-anterior view (2) lateral view (3) oblique view and (4) vertical view.

In the majority of cases the postero-anterior and lateral views alone will give the information desired. The other views elucidate special points not made clear in the postero-anterior and lateral views. Stereoscopic pairs in postero-anterior and lateral positions often give additional information.

The oblique view is made by first placing the patient and tube in the usual position for making postero-anterior view and then displacing the tube laterally about two inches. This projects the sphenoid sinus to one side of the nose, displaces the petrous portion of the temporal bone clear of the antrum on one side, and brings the ethmoid of one side into fuller view. By making a second exposure with the tube displaced to the opposite side, comparison of the two sides may be made.

The vertical view is made by placing the patient chin over the edge of a table, the tube being placed above the vertex. This view shows the sphenoid sinuses side by side.

Examination of the frontal sinuses reveals their extent laterally and vertically and the depth teroposteriorly. The thickness of their walls is also manifest and their accessibility through the nose. The presence and location of septa are

determined. These are important factors if a drainage operation is contemplated. The presence of air-cells in the crista galli has a bearing on the possibility of meningeal infection from the frontal or ethmoid sinuses. The determination of the thickness of the walls of the frontal sinus is important for these reasons:

1. A thin posterior wall favors the spread of infection to the meninges.
2. A thin floor favors the spread of infection to the contents of the orbit.
3. A thick anterior wall may make operation very difficult or lead the surgeon to think the sinuses are absent.

Examination of the ethmoid cells gives information as to their size, the total area covered by them, and their relationship to the other accessory sinuses.

The latter point is important in considering the likelihood of infection spreading from one sinus to another.

Radiography of the maxillary sinuses demonstrates the following points: (1) the size (2) relation to other sinuses (3) projection of tooth roots through the floor and (4) presence or absence of an alveolar recess.

The third point is important as a likely avenue of infection in dental caries, the fourth must be considered when drainage operations are contemplated.

The facts to be determined in radiography of the sphenoid sinus are its size, the thickness of its walls, and its relationship to the sella turcica and the optic chiasm.

The two latter points are very important in case the chief danger—suppuration of the sinus—re extension to the meninges, to the optic nerve or thrombosis to the intracranial venous sinuses. Since the optic chiasm is often in direct relationship to the roof of the sphenoid sinus, the thickness of the bony wall is a very important factor in determining the likelihood of implication of the optic nerve in sphenoid infections. G. W. Gair.

Arrowsmith H. Malignant Hypernephroma of the Ethmoidal Region. *Laryngoscope* 9 6 1914.

The author reports the case of a colored male, 56 years of age, with history of obstructed left nostril and repeated attacks of profuse bleeding from that side. The mass was removed by snare.

Very profuse hemorrhage ensuing necessitating tamponing. A few days later the patient went home. The pathologist's report revealing the true nature of the growth, the patient was sent for and he reported that he had suffered several profuse attacks of hemorrhage while at home.

Physical examination revealed a distinct mass in the right upper abdominal quadrant and enlargement of a number of superficial glands in that region, many disseminated areas of consolidation in both lungs, a right suprascapular mass the size of hen's egg. For the next few weeks there was profuse bleeding. The left nostril was again

filled with a mass and a complete extirpation was decided upon. The left external carotid was ligated and the right supraclavicular mass removed. The nostril was exposed by a lateral rhinotomy after Moutre's method and a friable yellowish mass was removed which had involved and destroyed the entire left ethmoid region and the inner wall of the orbit. Bleeding was profuse and the patient died three hours after leaving the operating room.

The author states that this is the only case in which the nose was involved in a metastatic growth of hypernephroma although metastatic involvement of the larynx (one case by Menzel) and of tongue (one case by Coenen) are mentioned.

OTT, M. R. II

THROAT

French, T. R. The Tonsilloscope. *N. Y. M. J.* 916 611, 661

The instruments needed for internal tonsilloscopy or the examination of the tonsil *in situ* are a lens tube speculum or tonsil microscope and a slender lamp which can be placed behind, below or above the tonsil and buried within the various spaces between the tissues so that its light is not directly exposed to the eye. The tonsil microscope which is made in two sizes is a slender tube or speculum about six inches long inside of which at the end of a sliding tube is a lens of from five to eight diopters according to the visual needs of the examiner. The distal end of the microscope is beveled and shaded and has an aperture the diameter of which is in one instrument one-quarter of an inch and in the other one-eighth by one quarter of an inch. The instrument with the largest aperture is intended for the examination of the free face of the tonsil and the capsule as well. That with the smaller aperture is intended for the examination of the capsule only.

The lamp is of one candle power and is enclosed in a small metal case with a glass window at or near its distal extremity. It is attached at an obtuse angle to an electric light shank which connects by a cable with a tungsten battery balanced in size and power to the candle power of the lamp. The tonsillar substance can however be more effectively transilluminated with a double lamp which should be preferred in all examination in which the tonsil is large enough to hide the glass windows from view.

By this method of transilluminating the tonsil lights up in much the same way as does a stained glass window brilliantly transilluminated from the opposite side. The outlet of the tonsil microscope is then applied to any and every surface of the luminous tonsil not occupied by the lamp including a large part of the surface of the capsule even if there are no adhesions to the anterior pillar. Many of the conditions within the tonsil can in this way be seen directly. The meaning of the varieties and shades of coloring is a matter of interpretation

which has been developed from experimental color studies made in association with the anatomical histological and pathological findings.

When the tonsil is that of health or nearly so it is relatively translucent and permits a considerable amount of light into its contents. When however it is the seat of disease it is less translucent in proportion presumably to the number and virulence of the bacteria in the pathogenic material present and the consequent inflammatory reaction produced by them so that in extensive disease it is impossible to detect anything beyond collections of detritus and pus lying close to the surface.

Another instrument which the author calls the external tonsilloscope is used for the examination of exploratory sections removed from the tonsil at the beginning of operations and for the study of the tonsil as a whole or in part after operations. It consists of a simple microscope on a light screen and a powerful electric lamp suspended together from a crane. The object in their suspension is to make it possible to conduct the examination without a break in surgical cleanliness. The lens in the microscope has a magnifying power of six diameters. It is fitted into the proximal end of the tube of the microscope and has an adjustable focus. The microscope tube tapers to a size at the distal end which can be readily covered by a section or the whole of the tonsil. The specimen is caught upon a hook at the distal end and left in position for leisurely study. The lamp is the Nernst of 350 candle power.

The former procedure internal tonsilloscopy is of more practical significance.

The following classification of the conditions found in the tonsils is offered:

- 1 The tonsil of health
- 2 Functional stimulation or mild disease the doubtful class
- 3 Superficial abscesses
- 4 Apparently acute or large foci of detritus and pus occupying restricted areas.
- 5 Considerable general disease
- 6 Extensive general disease

The picture of the tonsils as seen through the microscope in the above classifications are then given as follows:

1 The color of a tonsil in health is warm amber but the passage of light through a thin edge of a tonsil or through a very small tonsil of health even in an adult produces a color more like that of rock candy. In the tonsil microscope small arteries are seen coursing upon the surface and to some extent in the stroma while here and there in the substance of the gland appear small round red spots like flies in amber.

2 In the doubtful class functional stimulation or mild disease there is a departure from the normal indicated either by a uniform pink-amber color or by involving the entire tonsil or by hyperemic blushes covering small areas of the amber field.

3 In the class, superficial abscesses, blind ab-

abscesses are seen just under or near the epithelium on the free face of the tonsil which transilluminate as dark or black discs according to their proximity to the surface the nearer the surface the darker the shade. In the tonsil microscope abscess formations when present may also be found directly under the capsule.

4. The class characterized by apparently active or large foci of detritus and pus occupying restricted areas. The prominent feature found upon examination of this group, with the tonsil microscope and transillumination is that the hyperemia is in more or less sharply defined areas set in a field which may not be far removed from the color of the tonsil in health.

5. In the fifth class in which there is considerable general disease there is uniform though comparatively light hyperemia indicating that there is quite a number of collections of detritus scattered throughout the tonsil, but probably no pus.

6. The sixth class is marked by extensive general disease, which implies the honeycombing of the crypts and the substance of the tonsils with detritus and pus. The coloring in transillumination is uniform and of the deepest shade seen in the tonsils, and always corresponds to that of the anterior pillar.

The following conclusions have been offered as a result of a study of 666 tonsils in and from 333 operations upon children and the study of tonsils *in situ* in a large number of youths and adults.

1. All enlarged tonsils in subjects above the age of eight years are diseased.

2. Enlarged tonsils in subjects below the age of eight years may or may not be diseased, and whether they are or not can be determined only by examination with the tonsilloscope.

3. The tonsils in subjects above the age of childhood are often, and without much doubt oftener than we now know, the seats of foci capable under certain conditions of producing local and systemic infections.

4. In many subjects with tonsils in classes 2, 3, and 5 it has been proven that they are the source of systemic infection, and total excision holds out the only hope of complete and permanent relief.

5. Tonsils which are the seat of extreme disease and which are, therefore, seen to be excessively hyperemic, bleed freely when cut into.

6. The inner wall of a peritonsillar abscess can be located and mapped out with ease.

OTTO M. RORT

Adams, E. Sarcoma of the Tonsil. *Am Med* 9 6 21, 320

The case reported is that of a woman aged 53 who had a small ulceration about the size of a dime on the left tonsil. The tonsil was movable but the cervical glands anterior to the sternomastoid muscle were enlarged. The clinical diagnosis of sarcoma was made and the high-frequency current was applied daily both to the tonsil locally and externally to the glands but with no effect. At the same

time Coley's serum was used the injections having been made in the gluteal region, subcutaneously. The dose at first was one minium but it was pushed to 15 minims when the patient had a severe reaction. There was no influence on the growth, however consequently radium therapy was used, but the only result was severe radium burn. The tonsil then was removed by means of a snare and examined microscopically when a diagnosis of round cell sarcoma was made.

Radium was again used but in spite of this the glands in the neck and axilla increased and later there was evidence of pulmonary metastasis with sudden death evidently from pulmonary embolism. (OTTO M. RORT)

Kenyon, E. L. and Kradwell W. T. A Study of the Physicochemical Function of the Palatal Tonsil. *Ill Med J* 9 6 120, 426.

The authors study resulted in the following conclusions:

1. The tonsil serves as an absolutely necessary factor in providing a barrier for the action of the palatoglossus muscle.

2. The function of the tonsil with reference to the palatopharyngeus is to afford support and protection of great importance to its normalcy of action.

3. Tonsillectomy serves to destroy not merely possible lymphatic function of the tonsil but also to either disturb or destroy an important physicochemical function, on which is capable of being clearly demonstrated.

4. More or less impairment of the action of the depressor palatal muscles must occur in practically all cases following tonsillectomy regardless of the delicacy of operative technique or the particular form of operative procedure adopted but delicacy of procedure and method of operation are not of course to be considered unimportant.

5. To consider the present operation of tonsillectomy as a final settlement of the operative approach to the tonsil is premature and erroneous. The whole tonsil question requires further anatomical, pathological, and operative study in order if possible to readjust the operative approach to the organ to the new knowledge which is accumulating.

OTTO M. RORT

Farrington P. M. Tonsillectomy According to the Sluder Technique. *South Med J* 9 6 1, 456

The author regards properly performed Sluder operation as the simplest, safest and best method of performing tonsillectomy. He regards tonsillectomy as a hospital procedure to be performed in the morning after the patient has been thoroughly examined by an internist and properly prepared for general anesthesia.

With the patient on his back, under ether anesthesia the operator removes the tonsil with the Sluder instrument and fills the tonsillar fossa with a gauze pad. After inspection of the tonsil to see if it is intact, he removes the gauze sponge, inspects

the fossa stops all bleeding with clamps which he allows to remain on for a minute and proceeds with the other tonsil. In a series of 175 cases operated upon by this method the author had only 5 failures all of whom were adults.

ELLIOT J. PETERSEN

Dupuy H.: A Study of Five Hundred Tonsillectomies with the Beck Pierce Tonsillectome. *South M J* 1906 453

The author claims many advantages for tonsillectomy performed with the Beck Pierce tonsillectome basing his opinion on data obtained in five hundred consecutive cases operated upon with this instrument by a modified Sluder technique. Among the advantages he claims that enucleation can be quickly performed, danger of hemorrhage is minimized, there is less traumatism and local reaction than by other methods, though he admits these advantages are obtained in operations on children under the age of ten years and that this method is not ideal in operating upon adults.

As to the technique the tonsil is lifted upward into the supratonsillar region and gently pushed through the ring of the tonsillectome with the index finger. The mass is then seized with a grasping forceps meanwhile keeping the index finger against the tonsil and the wire loop slowly drawn thus enucleating the tonsil with a thin layer of capsule and leaving the greater part of the capsule in the fossa as a protective lining.

ELLEN J. PATTERSON

Escalada C. Fractures of the Larynx (fracturas de la laringe). *P. med. y g. t.* 1906 43

The author has made an elaborate study of laryngeal fractures. In some cases the mechanism of a laryngeal fracture is evident and does not call for discussion. In others however the clinical manifestations admit of different interpretations. Escalada has made six series of experiments on the cadaver using anteroposterior pressure upon the thyroid, the cricoid, and the laryngeal conjunctive then repeating this series using transverse pressure. He found in general that a pressure of 55 to 80 kilograms was necessary to fracture the larynx but that the force varied with the age of the subject and the degree of ossification.

In a case of fractured larynx the treatment in general will be confined to prevention of asphyxiation pending intervention by a specialist. Tracheotomy is recommended for the prevention of recurrence of asphyxia but some recommend this as a precautionary procedure to obviate the accidents which might occur.

W. A. BRENNAN

MOUTH

Merritt A. H.: The Roentgen Ray in Dental Practice. *Am J Roentgenol* 9 6 311 364

The author discusses the use of the roentgen ray in the following conditions: (1) periapical infections, (2) pyorrhea alveolaris, (3) missing and impacted teeth, (4) facial neuralgia.

1. Periapical infection. When a tooth loses its vitality it is only a question of time when it becomes infected. The acuteness or chronicity of the symptoms of this infection depend upon the number and virulence of the organisms engaged. If the infection lapses into the chronic state the pain subsides and the patient is usually unconscious of its presence. A discharging sinus may be present or a blind abscess may surround the root of the tooth. Differentiation between these two conditions cannot be made by the roentgen ray nor is the severity of the infection disclosed by roentgen examination. Every non vital tooth should have the pulp removed, the root canal sterilized and filled to the end in order to prevent trouble which is certain to come unless this is done. If abscess is already present in addition to this the abscess should be opened through the alveolar process, curetted, packed with sterile gauze and allowed to heal from the bottom. If the end of a root extends into the cavity it should be amputated. Teeth treated in this manner are not a menace to health and should not be indiscriminately extracted. Where extraction is necessary it is advisable to first procure cultures for autogenous vaccines as the secondary constitutional symptoms do not always clear up with the removal of the exciting cause.

2. Pyorrhea alveolaris. The amount of destruction of bone in this condition is not always correctly shown by roentgen examination. If the necrosis occurs on the labial or lingual surfaces of the tooth it will not be visible on the roentgenogram. If it occurs on the lateral surfaces only the condition may appear to be worse than it really is.

3. In missing or impacted teeth the roentgen ray is indispensable not only to demonstrate the presence or absence but also the relative position of the teeth in question.

4. Facial neuralgia. If this trouble is caused by pulp nodules, or by enlargement of teeth roots (hypercementosis) the roentgen ray is of great diagnostic value. The author lays great stress on the fact that it is seldom necessary to ray the entire mouth if proper inspection is made previously. Pyorrhea is easily identified while periapical infections always occur in non vital teeth. The only thing then left to ray are malposed teeth which are usually molars.

SURGERY OF THE NERVOUS SYSTEM

Paralysis of the peripheral nerves in war injuries: operative considerations. E. DUBOUR. *Rev de chir* 9 6, 11, 337.

The value of the clinical signs permitting the recognition of injuries of the peripheral nerves, complete nerve-section, its functional restoration. A. PERRAS. *Rev neurol*, 9 6 xliii, 477.

Injuries to peripheral nerves and their surgical treatment. F. C. PONSARD. *Med. Press & Circ* 9 6 cl 5.

Neurolysis. E. DUBOUR. *Lyon chir* 9 6 xlii, 58.
A case of Erb-Duchenne paralysis due to bullet wound of the fifth cervical nerve, spinal accessory anastomosis recovery. G. L. PARKER. *Lancet*, Lond 9 6 cxc.

Paralysis of the external popliteal sciatic nerve: liberation of the nerve followed by immediate functional restoration. AUVER. *Bull. et mém. Soc. de chir. d. Pa* 9 6 xiii, 79.

Late recurrence of pain necessitating new intervention in patient operated for radial paralysis with palsy, completely cured within year. C. WALTHER. *Bull. et mém. Soc. de chir. d. Pa* 9 6 xlii, 695.

The functional value of nerve cicatrices: the currents observed in the course of interventions. L. BRIDGES. *Lyon chir* 9 6 xlii, 500.

The clinical signs of the complete section of the radial nerve of functional restoration. A. PERRAS. *J. de méd. de Bordeaux* 9 6 lxxviii, 76.

Nerve-sutures. J. A. STUART and C. DUBOUR. *Bull. et mém. Soc. de chir. d. Pa* 9 6 xxi, 66. [377]

Return of motility and sensation after nerve-suture in case of complete section of the radial nerve. PICHOT. *Bull. et mém. Soc. de chir. d. Pa* 9 6 xlii, 675.

Nerve prostheses—radial, sciatic, external popliteal, and median. J. PARV. *Rev. gén. de ch. et de thérap.*, 9 6 xxx, 40.

MISCELLANEOUS

Clinical Entities—Tumors, Ulcers, Abscesses, etc.

Cases illustrating the faulty treatment of superficial malignancy. H. H. HARRIS. *J. Am. M. Ass.* 9 6 lvi, 829.

Some precancer conditions. W. L. GROUND. *Wb. M. J.* 9 6 xv 515.

Cancer as non surgical disease. L. D. BULLEY. *N. Y. St. J. Med.* 19 6 xvi, 591.

Impressions gained from clinical observation of cancer. W. J. PERRY. *Virg. M. Semi-Month.* 9 6 xii, 65.

Report of two cases of idiopathic hemorrhagic sarcoma, one presenting unusual features, the special methods of treatment and investigation. T. C. GILCHRIST and L. W. KETRON. *J. Cutan. Dis.* 9 6 xxi, 429.

Contribution to the chemical study of tumors. A. RORRO and N. GALLO. *Prespe. méd. Argent.* 9 6, No. 3, 378. [378]

Malignant gizzards treated by Baccelli's method. G. T. VILLA. *Rep. de méd. y cir. Bogotá*, 9 6 vii, 304. [378]

A new classification of neoplasms and its clinical value. W. C. MACCARTHY. *Am. J. M. Sc.* 9 6 cl, 709.

Thoracic actinomycosis. J. APRAJO. *Teas. Buenos Aires*, 9 5.

A new theory of the function of the lymphocytes. D. MEXERDIE. *Med. Rec.* 9 6 lxxvii, 046.

Complete cretinism with normal mentality. HOGAN. *A. J. Obst. N. Y.* 9 6 lxxiii, 5.

Epithelioid gonorrhea developed subsequent to violent transmission of the shoulder. DEPLANT. *Prespe. méd.* 9 6 p. 333.

Case of acute senile hyperthyroidism. F. SAKI. *Siglo méd.* 9 6 liii, 378.

Studies of the basal metabolism in disease and their importance in clinical medicine. J. H. MEANS. *Boston M. & S. J.* 9 6 cxxxv, 804.

Amesbic cysts. P. RAY UT and G. KROUVITZ. *Prespe. méd.* 9 6 p. 239.

Cachexia of hypopharynx origin. SHIMOWSKI. *Meuschen. med. Wchnsch.* 9 6 xlii, 443. [378]

Dermoid cyst of the ovary operated upon after twenty three years. C. WALTHER. *Bull. et mém. Soc. de chir. d. Pa* 9 6 xii, 1256.

A case of echinococcus pulmonalis. E. ORTIZ. *Seminario méd.* 9 6 xlii, 606.

Preventive medicine as applied by chronic pyogenic infections. J. H. GARDNER. *J. South. Car. M. Ass.* 19 6 xii, 7.

The diagnosis of the internal secretory disorders, the detection of the simple thyroid dyscrasia. H. R. HARRIS. *West. M. Times*, 9 6 xiv, 338.

Myopathy related to disorders of internal secretions? G. P. MCCORM and S. D. W. LEONARD. *Med. Rec.* 9 6 lxxvii, 043.

Constitutional effects of surgical focal infections. E. LADINAC. *Prespe. méd. Argent.* 9 6 xiv, 687.

Adenoma in surgery. K. T. M. KIRK. *Am. Med.*, 9 6 vi, 403.

Sera Vaccines, and Ferment

Vaccine and serum-therapy in everyday practice. W. C. WILKINSON. *Am. J. Clin. Med.*, 9 6 xlii, 509.

Vaccines their uses and abuses as determined by the principles of infection and immunity. H. GARRELY. *Long Island M. J.* 9 6 x, 33.

Vaccine therapy and other treatment in some vulgaris and furunculosis. H. H. FOX. *J. Am. M. Ass.*, 9 6 lvi, 3064.

Blood

A method for the determination of the alkali reserve of the blood-plasma. W. M. MARRIOTT. *Arch. Int. Med.* 19 6 xlii, 820.

Importance of the lymphocytes of the blood. M. BEAVER. *Rev. Assoc. méd. Argent.*, 9 6 xiv, 54. [378]

The non-protein nitrogenous constituents of the blood and the phenolphthalein test in children. J. S. LEOPOLD and A. BERGMAN. *Am. J. Dis. Child.*, 9 6 xi, 43.

Vicious circles associated with disorders of the blood. J. B. HURRY. *Practitioner*, Lond 9 6 xcvi, 6.

Importance of the physiologic conditions on the immediate gravity of gunshot wounds. *LA VESPE*. *Presse med.* 1916 p 301.

Trench foot tetanus. *C G DAVIS* and *J J HILL*. *J Am M Ass* 1916 lxv 10.

Contribution to the study of the etiology of trench-foot. *S DUFLEPINE*. *Intern J Surg* 1916 xxx 3.

Experiences of gaseous gangrene in a trench. *H FREUND*. *Beitr Klin Chir* 1916 44.

Gaseous gangrene observed in the field. *C CAMPBELL*. *Gaz Med* 1916 11.

Notes from the Medical General Hospital in F. *J M ELDER*. *Can M A J* 1916 4.

The Hollister-Ashland Laboratories

Announce the consolidation of the B. K. Hollister Laboratories and the Ashland Raw Catgut producing concern, both long and favorably known in their respective fields, and offer to surgeons and hospitals the service and products of the only catgut ligature sterilizing organization in the world—having its material under the same expert bacteriologic observation from the slaughter of the animal to the finished tube.

As we treat it, the gut obtained in a sterile condition from selected healthy animals never knows infection.

Top and Side View of the Ideal Container

Hollister's Ovitubes mark the first real advance in ligature containers since the origination and introduction by us of the label enclosed round tube. Operating room convenience is here served in a tube which cannot roll, breaks with a sharp clean fracture and reduces packing bulk by nearly one half.

In these Tubes of Distinction we offer a complete selection of our incomparable ligatures and sutures.

See That Little Patch?

It can't come off because it's really vulcanized to the glove—that's just why the

EZ SELF-CEMENTING SELF-VULCANIZING PATCH

is saving many dollars in hospitals everywhere for surgeons who used to discard punctured or torn gloves because it took too long to patch them—even then it wasn't safe. But now they use the E. Z.

Takes only minute to do it—little sandpaper to rough the rubber around the puncture, drop of gasoline on the patch and on it goes. Then toss the glove into the sterilizer or boil it a few minutes when it comes out, E. Z. patch is a part of the glove. It has vulcanized right to it. Can't tear or pull off. Imagine anything more simple or clean to handle? And it's non-poisonous, non-infecting!

A trial envelope containing 12 E. Z. Patches with full directions for use. Hospital size package, 100 Patches for \$1.00. Sample on request.

THE E. Z. PATCH CO Akron, Ohio

HAS NO PISTON TO STICK

just when you need hypodermic the most. No matter how careful you are, or how good the syringe, if it has a piston it will sometimes stick. With the Unit you screw the cap, withdraw the stylet and know absolutely that it will always work. In addition the instrument and dose are rigidly aseptic doing away with flame and questionable city water. Camphor in oil, in particular, is being used in the Unit by thousands of physicians because it serves the tedious filling of the barrel. As there is no packing to be ruined, it is the cheapest and best way of giving this preparation. You will get easier and more effective medication with the Unit because there is nothing to be removed, nothing to be sterilized, no parts to adjust.

If you will send your dealer, ten and 10c in stamps we will gladly send complete Unit that you may see fit of convenience for yourself.

Actually Shot from Guns

Puffed Wheat and Puffed Rice are actually shot from guns. This is done to explode every food cell. The result is easy complete digestion. Every atom of the whole grain feeds.

This is the process invented by Prof. A. P. Anderson formerly of Columbia University.

The grains are sealed in guns. The guns are revolved for sixty minutes in a heat of 550 degrees.

This changes to steam the trifle of moisture which lies within each food cell. And a grain of wheat contains 125,000,000 of them.

When the guns are shot that steam explodes. Every food cell is thus blasted to pieces. The grains are puffed to bubbles eight times normal size.

These are delicious whole-grain food, airy, flaky, toasted, crisp. But we talk them to you because they mean whole grains made wholly digestible. And that was never done before.

For Mother and Child

23/1

After prolonged lactation a mother's milk usually decreases in quantity and nourishment. It is then that a properly prepared liquid extract of malt and hops would not only increase the volume of breast milk but the amount of its fat content. But to accomplish this, it must be a real extract of malt and hops and not a cheap imitation.

ANHEUSER-BUSCH'S
Malt-Nutrine
TRADE MARK

is the recognized standard of medicinal malt preparations, and is prescribed by eminent physicians for the mother and child at the nursing period. It is made of the choicest barley malt and Saazer hops and contains all the soluble substances of these two materials.

Albee's Electro-Operative Bone Set

equipped with

SPIRAL OSTEOTOME

Dr. Charles Harrison Frazer's spiral osteotome attachment is a valuable addition to the Albee bone set.

It is devised for osteoplastic and general skull work and equally adapted for laminectomy operations.

It cuts a smaller curve than any other instrument made.

When fitted with this osteotome attachment the Albee set becomes almost universal in its possibilities.

If you already have an Albee set, merely send us your right-angular saw and we will fit same with the Frazer osteotome for \$20.00. Price of right-angular twin saw with Frazer osteotome, complete as illustrated, \$80.00.

Let us send you our special circular showing the newest instruments for bone surgery.

Sunrise Slumber

The Teter Method for PAINLESS CHILDBIRTH

Almost all physicians and surgeons are familiar with the Teter Hospital Outfit. Doctor Teter recently perfected an Obstetrical Apparatus embodying the same principles as the Hospital Apparatus.

The Teter Gas-Oxygen Obstetrical Apparatus

is provided with

REGULATORS which must be used to reduce the high pressure of the gases and allow them to flow gently, easily and evenly.

GAUGES which show the pressures to which the gases have been reduced.

VAPOR WARMER for heating the gases, thereby enabling the anesthetic to induce analgesia and anesthesia more quickly and gently. By using warm gases, saving of from one-third to one-half is made.

EIGHT-FEET of the gases through water, which shows the Doctor how much of each gas he is using.

REBREATHING BAG, enabling the patient to rebreathe the gases, thereby reducing cost of same.

ETHER ATTACHMENT for delivering small percentages of ether for unconscious cases or for use in office practice.

PORTABLE. Special Instructions Unnecessary.

Devised by Dr. Charles K. Teter, the recognized leading Nitrous Oxide-Oxygen Anesthetist.

Newer Blood Tests

for Rheumatism, Arthritis, Gout, Nephritis, Uremia and Diabetes

In diabetes it is desirable to determine the sugar content in the blood, since this may be high, while the glycosuria may be low owing to inefficient kidney function. In diabetes with acidosis the carbon dioxide determination is useful since any considerable increase indicates a grave condition.

For differential diagnosis between gout arthritis and rheumatism the estimation of uric acid and non protein nitrogen in the blood is of assistance. In gout uric acid only is increased in arthritis both the uric acid and the total non protein nitrogen are high while in rheumatism both are normal. More detailed information on request.

on the Symptomatology of **GAS OXYGEN** analgesia and anesthesia; the technique for nasotracheal intubation in abdominal surgery; tonsillectomy, eye, ear and nasal operations; the technique for producing analgesia in obstetrics.

The McKesson Apparatus

has opened the way to more thorough operations on the eye, ear, nose and throat through its **INTERMITTENT FLOW** construction. It also gives the abdominal case a greater degree of safety, comfort, and shorter convalescence than obtained by other methods. The combination of the detachable rebreathing bag (the intermittent flow—flow when you inhale only) and accurately graduated mixtures of gas oxygen or gas-air and an emergency valve for inflating the lungs with pure oxygen—all in an automatic machine—are the features unique in the McKesson, giving it efficiency and ease of administration, its cost per hour so small that expense is no longer an item of consideration.

Let us send our Catalog, which explains the McKesson Model F Apparatus and describes its construction and principles in detail.

Sterilized Solutions in Glaseptic Ampoules

(FOR HYPODERMATIC USE)

SOLUTIONS IN AMPOULES have earned the approval of the vast majority of physicians and surgeons of America and Europe. They have many advantages over those prepared in the ordinary way. In the first place—and this is important—they are always ready for use. With the ampoules at hand the physician has no need to wait until water can be sterilized and cooled—he can make a hypodermic injection instantly. Then again, each ampoule contains a definite quantity of medication, insuring accuracy of dose. The solutions, too, are aseptic; they are permanent.

◆ ◆ ◆

SEND FOR THIS BOOK

We have just brought out a new edition of our Ampoule brochure. The booklet comprises 70 pages in addition to the cover. It contains a full list of our Stimulated Solutions, with therapeutic indications, description of packages, prices, etc. It has convenient therapeutic index. It includes useful chapter on hypodermic medication. Every physician should have the book. A post-card request will bring you a copy.

DR CHARLES GEIGER'S Electro-Operative Surgical Bone Instruments and Accessories

Used and recommended by Dr. John B. Murphy, Dr. Fred H. Allen, Dr. W. J. and C. H. Mayo

The instruments are especially made of transparent steel, allowing an examination of the metal to keep the corners from turning, and are made of the best material. A few of the many advantages of the instruments are: 1. They are made of the best material. 2. They are made of the best material. 3. They are made of the best material. 4. They are made of the best material. 5. They are made of the best material. 6. They are made of the best material. 7. They are made of the best material. 8. They are made of the best material. 9. They are made of the best material. 10. They are made of the best material. 11. They are made of the best material. 12. They are made of the best material. 13. They are made of the best material. 14. They are made of the best material. 15. They are made of the best material. 16. They are made of the best material. 17. They are made of the best material. 18. They are made of the best material. 19. They are made of the best material. 20. They are made of the best material. 21. They are made of the best material. 22. They are made of the best material. 23. They are made of the best material. 24. They are made of the best material. 25. They are made of the best material. 26. They are made of the best material.

Dr Charles Geiger's Orthopedic and Fracture Extension Device

in cases orthopedic and fracture work, especially in the lower extremities, gives clear access and removes the patient from the hospital while the patient is in the hospital. The device is portable and can be quickly attached to any operating table.

DR CHARLES GEIGER,

St. Joseph, Mo., U. S. A.

A number of competent electrical engineers agree that the "Snook" is the pre-eminent X Ray Transformer. A Snook Machine has been operating in the research laboratories of the General Electric Company for several years. The Eschenbach Company have developed their X-Ray plates with "Snook" Transformer. Recently, a number of high-precision Electrical Engineers of the Westinghouse Electric and Manufacturing Company selected the Machine pictured above. We appreciate the compliment. Requests for Bulletin No. 106 will be complied with promptly.

Scudder's Fractures

NEW (8th) EDITION

As usual Dr. Scudder has given his book a thorough revision, adding much new matter and 63 new illustrations. New material has been included on autogenous bone graft, on delayed union and non-union fractures of the jaw, the acetabulum and the great tuberosity of the humerus and separation of the lower epiphysis of the femur. While this work is called *Treatment of fractures of bones*, it runs large in great prominence a proper treatment can be instituted only after correct diagnosis. It is a work on fractures designed for the general practitioner—the man in active practice—and therefore confines itself principally to the practical sides of the subject—diagnosis and treatment.

Oct. of 7 parts with illustrations. By C. ARTHUR L. SCUDDER, M.D., Surgeon to the Massachusetts General Hospital, Boston. Cloth, \$6.00 (5s.) net. Half Morocco, \$7.50 net.

Keen's Surgery

SIX VOLUMES

There is no part of the medical world in which Keen's Surgery is unknown and read and followed. This world-wide circulation is due alone to practicality. The 8 contributors to Keen's Surgery represent leading authorities from two continents. Keen's Surgery has been adopted by the United States Government. It has been translated into Spanish. It is now in its eighth printing. Keen's Surgery is a world-wide circulation. Consultation of this work is made extremely easy and rapid by a general index to the entire volumes arranged with an alphabetical word at the head of each column—like a dictionary. In addition, each volume has its own index.

Six vols. of 7 parts each with 300 illustrations. 7th ed. Edited by W. W. KEEN, M.D., LL.D., Hon. F.R.C.S. (Ed.) and LL.D. Per volume, Cloth, \$5.00 (3s.) net. Half Morocco, \$6.00 net.

Moynihan's Abdominal Operations

THIRD EDITION

This third edition was issued to convenience in two handsome volumes totaling 600 pages. It is a personal record of Moynihan's operative work. You get his own successful methods of diagnosis. You get his own technique. You get the bacteriology of the stomach and intestines, sterilization and preparation of patient and operator. You get complications, sequelae, and after-care. Two entirely new chapters in this edition are *Excision of Gastric Ulcer* and *Complete Gastrectomy*. Some 85 new illustrations have been added, making a total of 385 superb illustrations showing you every step of every operation—really an atlas of abdominal surgery.

Two vols. of 7 parts each with 385 illustrations. By DR. BENJAMIN MOYNIHAN, M.S., LL.D., F.R.C.S. (Lond.) and F.R.C.S. (Ed.). Per set, Cloth, \$10.00 (6s.) net. Half Morocco, \$12.00 net.

Albee's Bone-Graft Surgery

RECENTLY ISSUED

Dr. Albee's bone-graft methods, particularly his iliac bone grafts, are revolutionizing bone surgery. In this new work you get for the first time all Dr. Albee's successful technique and its practical application. You get a full and clear description of his electric motor operating outfit and the technique of its use—illustrated. The section on fractures covers 100 pages and contains 100 illustrations, taking up grafting in every kind of fracture. Remodeling the hip-joint is given you in detail and every step of the technique clearly shown. You get some 85 pages on the bone-graft treatment of Pott's disease and other spine lesions.

Oct. of 7 parts with 100 illustrations. By DR. HENRY ALBEE, M.D., Professor of Orthopedic Surgery, New York Post-Graduate Medical School. Cloth, \$6.00 (5s.) net. Half Morocco, \$7.50 net.

THE LINCOLN RUBBER CO
AKRON OHIO

This valve makes possible the first hand-operated resuscitation machine employing the only principle recognized as correct by physiologists—accurately measured pressures. It's an exclusive feature of the

new type B Pulmotor

Up to the present, all hand-operated resuscitation machines have depended upon the skill and intelligence of the man at the pump—there being no controlling device interposed between the pump and the patient's lungs. Consequently the pressures varied, often to the serious detriment of the patient.

The Pulmotor Pressure Control Valve insures uniform, measured pressures, adapted to the specific needs of each case. Indicator Gages show precisely what pressures are being exerted, both of inhalation and exhalation.

Type "B" Pulmotor can be successfully used by even an unskilled operator. It weighs only 12 lbs. with carrying case and is instantly ready to be taken anywhere in emergency. Price complete \$115.

Order now to insure prompt delivery

Hay Fever Vaccine Mulford

For the Prevention and Treatment of

Hay Fever, "Fall" or "Autumnal" Type

Hay Fever Vaccine "Fall" Mulford contains the protein extract from the pollens of ragweed, golden rod and maize, dissolved in physiological saline solution and accurately standardized and may be used without preliminary diagnostic tests. If treatment does not give entire relief, skin tests may be made to discover possible hypersusceptibility to pollen not contained in the Vaccine.

Noon working in Sir Almroth Wright's Laboratory was the first to report successful results in the treatment or prevention of hay fever with subcutaneous injections of pollen extracts. Clowes, Lovell, Lowdermilk, Ulrich, Hitchens and Brown, Kessler, Manning, Cooke, Wood, Goodale, and many other scientists have amply confirmed Noon's work.

Hay Fever Vaccine "Fall" is furnished in

Packages containing 4 sterile glass syringes

of graduated strengths, \$5.00

In single syringes D strength, 1.50

Syringe A contains 0.0025 mg. extract of the pollen protein

B	0.005
C	0.01
D	0.02

In ordering Vaccine for Hay Fever occurring during the late summer specify "Hay Fever Vaccine Fall Type Mulford."

For Immunization against Hay Fever first dose (Syringe A) should be given at least 30 days before expected attack followed by B, C and D at five-day intervals. Syringe D strength Vaccine should be used at weekly intervals during the entire period of accustomed attack or until immunity is established.

For Treatment of Hay Fever the doses are given at five-day intervals, beginning with Syringe A, followed by B, C and D in order, followed with Syringe D at weekly intervals during the entire period of accustomed attack, or until immunity is established.

There are no contraindications to the therapeutic or prophylactic use of Hay Fever Vaccine Mulford so far as known. A small percentage of patients may be hypersensitive to the protein extracts, in which case the doses may be accordingly reduced.

Dependable Non-elastic Abdominal Support Camp Physiological Belts and Bands

Employ an absolutely new principle in adjustment which enables the physician or surgeon to secure the support or pressure at the point where it is required and to adjust it to the exact needs of the patient. This provides a simple but effective means of securing pads and bandages when needed in position with the assurance that they will stay where they are placed. This statement is made after severe tests on many subjects extending over months of actual use.

The illustrations show front views of the complete belt as applied to both men and women. Other forms supplied include band for attachment to the corset and adjustable corsets both of which provide the same simple and effective abdominal support.

Plate I, Men's Belt

Plate II, Women's Belt

Plate I shows this adjustable non-elastic support in the form of a man's belt. This band can be used with great success following abdominal operations and in the treatment of floating kidney and hernia. Complete support is afforded and the pressure is evenly distributed preventing constriction at any point and obviating many objectionable features of other types of belts.

Plate II illustrates the band as worn without a corset. Equal corset back being used in this type of belt. In the case illustrated the young woman aged 25 years has double ventral hernia. An operation proved unsuccessful and surgeon advised against second operation. Has worn Camp Physiological Belt for three months, with and without corset, regaining complete health and now able to do her own housework, including washing and ironing. The belt affords best relief and comfort he had not known for 18 years during which he had worn a truss.

DISEASES

OF THE

Kidneys, Ureters

AND

Bladder

BY
HOWARD A KELLY, M D

In Collaboration With
CURTIS F BURNAM, M D

No other work on urological problems has been written which covers the subject from the standpoint of the female as well as the male.

This work is to the field of urinary diseases what Dr. Kelly's gynecological works are to the field of female diseases—the most important and valuable contributions of the kind.

The methods of the authors are based upon careful analyses of several thousand cases personally handled by them during their long connection with the Johns Hopkins University and Hospital.

Greatest attention is paid to the common diseases rather than to those which are rarely presented to the general practitioner.

AMERICAN ATLAS OF STEREOROENTGENOLOGY

Edited and Published Under the Sole Auspices of THE NEW YORK ROENTGEN SOCIETY

Editors Leopold Jacobus, M. D., H. O. Imboden, M. D., William H. Stewart, M. D.

With associates and correspondents throughout the world

Publisher's Announcement

THE foregoing announcement marks another mile post in the advancement of medicine and surgery.

The membership roll of the New York Roentgen Society which as an organization has taken full command of this new enterprise is almost synonymous with the muster roll of those brave spirits, throughout the world, who have drawn from this new and often fatally exacting science its profoundest secrets, hence we believe the American Atlas of Stereoroentgenology will be at once accorded position among the foremost and most important of clinical publications of the age.

ITS SCOPE. The scope of this publication will be *CLINICAL* in the broadest sense elucidating Anatomy Physiology Morphology Organology and Pathology in the living subject in a more practical and graphic manner than ever before attempted.

It will give more intimate view of structure and organs in the living body more clearly define their relations to one another and to function, both under normal and pathological conditions, and thus tend to a clearer meaning of symptoms and signs and finally render the subject of Clinical Diagnosis less difficult.

ITS ILLUSTRATIONS. The illustrations will be almost exclusively Stereoroentgenograms—double Roentgenograms taken from different angles at almost the same instant.

ITS TEXT. The descriptive text will in each instance begin with the earliest procurable history of the case and follow it step by step until it reaches the Stereoroentgen Laboratory and where possible, verified in the operating post mortem room thus affording the greatest opportunity for clinical comparison.

ITS FORM. The American Atlas of Stereoroentgenology will appear quarterly as loose leafed journal, and each number will be provided with a neatly labeled case or cover giving it the appearance of a book or volume which will make it attractive when placed on the book shelf. The size of this case will be about 7 9 inches.

Each number will record about eight important cases and the advantages of this form of publication are manifold facilitating the study of each case and the Stereograms separately the correlation of cases for comparison and final grouping of the subject matter according to subjects or branches.

AS A JOURNAL. From issue to issue it will contain editorial comment and clinical articles illustrated by this incomparable method, that will keep pace with the latest thought and achievement in these newer methods of diagnosis.

AS AN ATLAS. From year to year it will add to the working library one complete volume, in four parts, of graphically demonstrated clinical material, that the entire world has been drawn upon to provide and which are recorded because of their extreme clinical value.

THE MATERIAL AND PRICE. The publishers frankly admit that the publication of this work is made possible through the generous co-operation of the members of the New York Roentgen Society in placing their records and priceless collections subject to requisition by the editors and that this co-operation makes it possible for the publishers to fix the price of the Atlas within the easy reach of all i.e., Ten Dollars annually.

IMPORTANT ANNOUNCEMENT

New 3rd EditionJust ReadyThoroughly Revised

INFECTIONS OF THE HAND

A GUIDE TO THE SURGICAL TREATMENT OF ACUTE
AND CHRONIC SUPPURATIVE PROCESSES IN
THE FINGERS HAND AND FOREARM

By ALLEN B KANAVEL, M D

Assistant Professor of Surgery Northwestern University Medical Department; Attending
Surg. Wesley and Cook County Hospitals Chicago

Octavo, 498 pages, with 161 engravings Cloth, \$3.75 net

THE importance of this work to all surgeons is demonstrated by the fact that it has passed so quickly through two large editions. The urgent demand for a third edition has given the author an opportunity to enhance the value of his monograph by a thorough revision and by the addition of new material in text and illustrations.

The enormous economic significance of infections of the hand is coming to be universally recognized. There is probably no other class of cases where malpractice is more common or unfortunate results of treatment more frequent. Therefore the subject of this book is of the greatest interest and importance to every surgeon and general practitioner.

The surgeon who does casualty work or has charge of industrial accidents will find this work invaluable and many deformed hands might be prevented if every practitioner were familiar with the importance of this subject and with the complete manner in which this book handles it.

Any physician who carefully follows Kanavel will have his conception of the subject completely clarified. The various chapters on treatment of different conditions are very full; the technique is well described and the after treatment is carefully given. Following each chapter a definite complete resume is given which will be found most helpful.

JULY 1916

NUMBER 1

THE TECHNIQUE OF SPLENECTOMY

BY DONALD C. BALFOUR, M.D., FACS, RICHMOND, MINNESOTA

THE more frequent recognition of certain chronic disorders of the blood particularly plenic anemia hæmolytic jaundice and pernicious anemia and the therapeutic value of splenectomy in these and other diseases have recently greatly extended the indication for splenectomy and suggested some observations on the technique of the operation. In our experience (especially in those cases in which technical difficulties are encountered) the operation has been facilitated by following a routine plan and by the precision with which the detail of such a plan are carried out.

Through a left Bevan incision (Fig. 1) its length depending on the size of the spleen the abdomen is explored. The suggestive frequency with which jaundice attacks of epigastric pain simulating biliary colic cirrhosis and gall stones occur in many of the diseases for which splenectomy is advocated necessitates an accurate record of the condition of the liver gall bladder and bile passages. Such observations will ultimately possess specific value in the elucidation of the obscure but unquestioned intimate relation ship between the spleen and the liver.

The dislocation of the spleen from its position against the diaphragm and the left kidney (Fig. 2) should be the first step in the actual removal of the organ. The separation of the diaphragmatic adhesion can usually be safely accomplished by the finger. If

it is found that the adhesions have acquired blood vessels of sufficient size to require ligation it is then even preferable in most cases to postpone such ligation (unless the vessels be reasonably accessible) until the spleen has been removed the bleeding being temporarily controlled by a gauze pack described later. In an occasional case however adhesions cannot be stripped with safety and they must be divided between long curved forceps care being taken to engage only the adhesions in the clamps. Hartmann and other have advised that the operation be abandoned when these adhesions appear formidable. However we have not recently found such conditions to be prohibitive to splenectomy although in some cases absolute hæmostasis has been secured with considerable effort.

Immediately the spleen has been dislocated a long hot abdominal pack is efficiently arranged in the space formerly occupied by the spleen until the entire area with which the organ has been in apposition is under firm pressure by the gauze (Fig. 3). This accomplishes two purposes. First and most important the oozing surfaces are compressed and as the bleeding is usually venous it is controlled without subsequent ligation if the pack (a point emphasized by W. J. Mayo) is left undisturbed until the actual operation is completed. Second an excellent support is provided for the safe manipulation and mobilization of the organ the division of adhesions and ligation of the main pedicle

Fig. 1. Breen's incision as adapted for splenectomy.

The spleen having been elevated in this manner its further connections are the main splenic pedicle with its peritoneal investment (the lienorenal ligament) the gastrosplenic omentum and in splenomegaly of long standing various adventitious adhesions. The most satisfactory isolation and treatment of the splenic pedicle is obtained by the preliminary division of the accessory adhesions as well as the peritoneal attachments and reflections. The gastrosplenic omentum should first be divided in sections as close as possible to the spleen, between ligatures. The only named vessels encountered are the vasa brevia, which arise from the splenic artery at variable points, pass to the greater curvature of the stomach, in this peritoneal

fold and finally anastomose with the left gastro-epiploic. In dealing with the upper edge of this gastrosplenic omentum it must be remembered that here the fundus of the stomach is normally in very close apposition to the spleen. It is necessary therefore always to determine the exact relationship and protect the stomach from injury in its separation from the spleen. In an earlier experience I accidentally included in a clamp and excised a small area of the wall of the stomach the resultant opening however being readily closed without post-operative complication. At the lower pole of the spleen there is an occasional fibrous attachment derived from the phrenocolic ligament, which with the other adhesions should be separately ligated.

The spleen may now be further mobilized by careful dissection of the peritoneal and fibrous coverings of the splenic pedicle. The localization of the tail of the pancreas is the important feature of this mobilization, and as the relationship of the organ is not constant it is necessary to inspect it in all cases. In some instances the tail is short lying against the renal surface of the spleen on the posterior aspect of the pedicle and it may be fitted so closely into the hilus of the spleen as to have acquired a concave edge. In other cases the tail is attenuated it is in front of the splenic vessels and in contact with the gastric surface while often it does not extend into the operative field.

Figure 4 shows the spleen turned turtle and represents a frequent relationship of the pancreas to the splenic pedicle. It is quite obvious that such a pedicle would not be ligated without including a portion of the pancreas. Figure 5 (frontspleen) shows that with the reflection of the lienophrenic ligament a better exposure is obtained of the tail of the pancreas that it can be detached from its original position by dissection and allowed to drop back from the hilus of the spleen.

Therefore after such dissection the splenic pedicle consists, from a surgical standpoint of the splenic artery and its veins. The artery in some instances has divided before reaching the hilus of the spleen, although it often continues as a single trunk well into the hilus

Rede from Todd's Anatomy

Fig. 2. Diagrammatic representation of the position of the gall bladder.

while the veins are always in two or more branches. The latter do not bear a fixed position as regards the arterial trunks lying in front in some instances and behind in other. They are always distinctly larger than the artery itself and their extreme friability must always be considered. The arrangement of the vessels of the pedicle is fan-shaped as in Fig 5 or 6 the breadth varying in different cases.

At this point it is possible to decide whether it is best to treat the pedicle *en masse* (Fig 6) or to ligate it in section (Fig 5 frontispiece). The latter method is to be preferred and the dissection of the pedicle is usually most advantageously carried out on its posterior aspect with the spleen tracted toward the midline. The extent to which the spleen can be lifted out of the abdomen by careful traction is surprising, if following the division of the

Fig. 3. Position of the gall bladder.

Fig. 4. Posterior surface of spleen exposed, showing tail of pancreas which lies in the splenic pedicle posterior to vessels. The pancreas should be dissected from its position before clamps or ligatures are applied.

peritoneal and fibrous investments of the pedicle certain of the lateral venous trunks are separately isolated and divided between ligatures (Fig. 5 frontispiece). It should again be emphasized that caution must be exercised in the degree of traction to which the pedicle is subjected and in the dissection of these veins. It is chiefly because of the normal tortuosity of the splenic artery that this elongation of the pedicle is possible and thus facilitates its secure ligation. We have recognized the advisability of first securing where it is possible the arterial supply so that the spleen may partially empty itself of its contained blood through the unclamped veins before these are ligated.

If on account of the arrangement of the veins and arterial branches, ligation in sections is not advisable ligation *en masse* by the two-clamp method, will prove a satisfactory and safe method. Two curved clamps

are arranged on the pedicle with a third clamp on the splenic side to control back bleeding and the spleen is removed. A double strand of No. 2 plain catgut is tied with moderate tension in the crushed line of the inner clamp as a partial control and a second strand is transfixed below the distal forceps as the actual control.

Having made certain by either of these methods that the pedicle is securely ligated the large hemostatic pack is removed the newly exposed surfaces inspected, any oozing points being separately secured by fine catgut on a needle and absolute hemostasis assured.

The disease or condition for which splenectomy is done governs largely the technical difficulties and risk of the operation. I have found for example that in pernicious anemia the removal of the spleen can be accomplished with comparative ease and safety. Although

Fig. 6. Retroperitoneal attachments separated, mobilizing spleen and permitting application of clamps. Pedicle to be divided at dotted line.

enlargement of the organ has been present in those cases in which we have advocated surgical treatment, adhesions are few and usually insignificant. The pedicle is as a rule small and in a relatively small percentage is its treatment complicated by the relationship of the pancreas. Furthermore the risk of the operation in this disease can be minimized by intelligent pre-operative treatment and observation as well as by the careful selection of the cases. There must be a rational basis upon which splenectomy in pernicious anemia is advocated, as well as strict recognition of the limits of operative safety. Splenectomy is definitely contra-indicated during an acute crisis or in a period when the patient shows a steady decrease in haemoglobin and red blood-cells or when

mental torpor, cord changes and oedema mark the terminal stages of the disease. Repeated transfusions from a suitable donor will frequently carry the patient through most critical exacerbations of the disease and the proper interpretation of the reaction following transfusion is essential. Further it is important that a satisfactory donor be available after operation.

In splenic anaemia splenectomy is associated with a higher operative risk and greater technical difficulties than it is in any of the more common diseases of the spleen. In the cases I have seen the spleen has been usually of large size, the vessels very friable and adhesions occasionally troublesome. Patients in the late stages of the disease are prone to develop fever, ascites, cirrhotic liver or severe

anaemia, which conditions contribute to the seriousness of the operation. The only instance in which I thought it inadvisable to attempt splenectomy was in splenic anaemia with great ascites, atrophic cirrhosis, and aneurismal splenic vessels. The friability of the veins in this disease was especially demonstrated in a baby 22 months old upon whom I performed splenectomy for typical splenic anaemia of the adult type.

The operation in haemolytic jaundice is of relatively little risk and there has been no particular difficulty in the removal of the spleen, although the organ is occasionally very large. It is however most important to avoid splenectomy during an exacerbation of the symptoms. Of the cases I have seen of this disease the only operative death occurred in a patient in whom I failed to realize the import of a subacute and subsiding acholuric crisis.

In those cases of cirrhosis of the liver associated with splenomegaly in which splenectomy is to be considered the spleen is often firmly adherent, and this fact together with the

poor general condition of the patient makes the operation rather hazardous. Nevertheless, in the cases we have selected for operation there has been no operative mortality and in two cases of my own most striking benefit has thus far followed the removal of the spleen.

In the rarer conditions such as syphilitic spleen and idiopathic splenomegaly the operation itself is not of great risk. It has been interesting to note the result of splenectomy in two cases of splenomegaly with specific history and positive Wassermann. In both of these it had been previously possible to obtain a negative Wassermann by salvarsan but it would become positive on discontinuing the treatment. Since splenectomy the Wassermann has remained negative.

From my own experience I have found that the features to be emphasized in the technique of splenectomy are (1) the abdominal exploration, (2) the dislocation of the spleen (3) the use of a hot gauze pack (4) the protection of stomach and pancreas from injury, (5) the preliminary ligation of adhesion and (6) the treatment of the splenic pedicle.

THE ETIOLOGY OF UTERINE PROLAPSE AND CYSTOCELE¹

By GIBBON FITZGIBBON M.D. F.R.C.P.I. DUBLIN, IRELAND
Gynecologist, Royal City of Dublin Hospital

THE subject of uterine prolapse and cystocele is one upon which there has been a great deal written and still new operations are constantly being described involving the removal of the uterus the distortion of parts and even the complete obliteration of the genital tract. There is surely some method by which the structures that normally support the uterus and vagina can be restored to functional activity and at the same time leave the organs which have to be supported intact in approximately normal positions and possibly capable of functioning—some operation which can be adopted as the all around basis for the surgical cure of the condition.

The majority of the cases of prolapse are met in women who have borne children. The prolapse is the result of damage caused by the passage of the foetus through the pelvis. In this act some structure which before labor was capable of supporting the uterus must be rendered incapable of doing so subsequently. The probability is that it is the same structure which is damaged in all or almost all the cases.

Prolapse occurring in nulliparous women is probably due to the same defective structures but there has not been any cause of laceration and therefore the prolapse must be due to some congenital defect of the supporting structures. This places these cases in a different category as the supporting structures even though not injured are incapable of supporting the uterus and any operation is subject to the doubt as to whether the tissues can be made capable of doing what they have already proved incapable of.

That the perineum and that part of the levator ani muscles which is torn with the perineum have no part in the support of the uterus is made evident by the fact that these structures may be extensively lacerated and this even when of long standing has no evident effect upon the level of the uterus. Lacerations

of these structures lead to the condition of rectocele in which the rectum bulges forward and downward into the vulva stretching the posterior vaginal wall in its lower half but leaving the upper half and the posterior fornix unaffected. The condition of rectocele is completely cured by a plastic operation upon the levator ani muscles and the perineum and the restoration of the parts to their normal condition.

On the other hand there are numerous cases of prolapse of the uterus where the cervix comes down to the vulva or even the uterus is completely extruded yet the perineum and levator ani are intact showing that some other structure is responsible for their maintenance and that the levator ani muscles are not capable of replacing this support. The facts definitely prove that the structures which support the lower half of the posterior vaginal wall have no part in the support of the uterus and therefore may be excluded in looking for the cause of prolapse of the uterus which must do damage to some structures above the level of the levator muscles.

The structure which is next met with in the pelvis above the levator muscles is the visceral or endopelvic layer of pelvic fascia and as I believe this is the main if not the sole support of the uterus and bladder I wish to give a very full description of its attachments and relations.

The pelvic fascia as shown by Cunningham (1) is a direct continuation of the abdominal fascia which is easily demonstrated as a continuous sheet lining the interior of the abdominal cavity and placed between the muscles and the peritoneum. The relative position of the pelvic fascia is identical and the visceral layer passes inward from the pelvic walls upon the upper surface of the levator ani and forms a complete fascial diaphragm to close the pelvic outlet. It springs in part from the back of the symphysis and the pubic ramus about the level of the junction of the lower

and middle thirds of the symphysis. From here it runs under the bladder and forms the true anterior ligaments of the bladder. It surrounds the urethra and is intimately connected with the base of the bladder upward along the walls of which it sends numerous fibers as well as others downward along the urethra. The fascia passing under the base of the bladder is closely connected with the anterior wall of the vagina and is continued backward to be attached to the supravaginal cervix where it helps to form the anterior vaginal fornix. This part of the fascia is very definite and usually described as the anterior true ligament of the bladder. It binds the bladder and urethra firmly to the posterior wall of the symphysis.

The next part of the pelvic fascia springs from the pubic ramus and the white line first at the level of the top of the obturator foramen and from the inner surface of the ischial spine. It runs inward above the levator ani muscles toward the vagina, bladder, cervix, and rectum and divides into the vesical, vesicovaginal, rectovaginal and rectal layers. The posterior part of the fascia here surrounds the rectum, and follows its walls as the rectal layer at the same time giving some support to the upper part of the posterior vaginal wall where that is in relation to the anterior wall of the rectum, and this part constitutes the rectovaginal layer. The anterior portion of this fascia is stronger and thicker than the rectal portion, and constitutes the vesicovaginal layer. As it runs inward toward the viscera it divides into numerous layers and becomes intermixed with loose connective tissue, which makes the demonstration of the whole fascia almost impossible close to the viscera. Nevertheless, the continuity can be shown and the different layers followed to lose themselves upon the walls of the viscera or to join the fascia of the other side. It is connected to the sides of the bladder and continuous with the anterior fibers of the fascia which pass under the base of the bladder. It passes across the pelvis between the anterior vaginal wall and the base of the bladder and is attached to the cervix uteri and the lateral vaginal fornices, above which it passes to reach the cervix and to become continuous with the

rectovaginal layer between the posterior vaginal fornix and the rectum and below the posterior cul-de-sac of peritoneum. The attachment of the fascia to the viscera is shown by Cunningham (2) in a dissection on the male and the same relations of the fascia to the viscera exists in the female, the vagina and the cervix uteri taking the place of the prostate.

In the region of the lateral vaginal fornices and the sides of the cervix, where the uterine vessels approach the uterus there is a very marked increase in the amount of fibrous tissue in which the uterine vessels run. This extra fibrous tissue forms a distinct fan shaped band lying between the lateral vaginal fornix and the side of the cervix in the plane of the broad ligament. This band has been described by Mackenrodt (3) as the transverse ligament of the cervix. It is part of the pelvic fascia and plays a part in the support of the uterus and vagina with the rest of the fascia from which it should not be dissociated. Hart (4) refers to this as the loose fatless tissue 0.8 inches thick with abundant blood vessels and lymphatics surrounding the lower portion of the uterus and upper portion of the vagina and says it was first described by Virchow and called the parametric tissue and is clearly shown by Freund in sections at the level of the supravaginal portion of the cervix.

This intermediate part of the endopelvic fascia between the ligaments of the bladder and the rectal layer is usually described as if it merely formed a sheet above the levator ani muscles, and the rectovaginal and vesicovaginal layers as though they passed between the viscera just above the fibers of the muscle, whereas the fascia is at a higher level in this part than the levator muscle. In section through the female pelvis this part of the fascia does not show up distinctly because the fascia is not in a distinct sheet and when the fibers are divided they retract in the loose tissue and do not show on the surface consequently the fascia is omitted in the region of the vaginal fornices and cervix, and that part which can be demonstrated as a sheet by dissections just above the levator muscles is depicted as the whole of the vesicovaginal

Fig. 1 Showing the origin of the visceral layer of pelvic fascia from the inner wall of the pelvis with the levator ani muscle arching just below it. a Visceral layer of the pelvic fascia springing from white line b coccygeus, c levator ani d parietal layer of pelvic fascia e pubic bone.

Fig. 2 Showing the division of the endopelvic fascia into the various layers: connection with the sacra, the abundance of fascia in the region of the vaginal fornices and cervix uteri and under the base of the bladder above the anterior vaginal wall. a Anal fascia b levator ani c recto-anal layer d recto-anal layer e vesico-anal layer f vesical layer g anterior ligament of bladder h lower layer of endopelvic fascia A 4 4 plane of section in Fig. 3

layer Where the fascia springs from the pelvic wall it can be seen as a distinct sheet but where it comes into relation with the viscera it loses the character of a sheet and divides up into various layers. The necessity for this is obvious when the dilatation which must occur during parturition is considered. If the fascia remained a single sheet where it is pierced by the cervix and the vagina the aperture would be incapable of dilatation whereas by means of the fascial fibers separating and running at different levels the supporting power is not diminished and the dilatation of the aperture is possible.

The description of the fascia in Cunningham's *Anatomy* together with his diagrams makes this perfectly clear. He deals with the fascia chiefly in the male subject and refers to this description when describing the fascia in the female. He says the rectum below the rectovaginal pouch of peritoneum is in apposition with the posterior wall of the vagina a layer of pelvic fascia the rectovaginal alone intervening. His illustrations show this part of the fascia distinctly as well as the vesicovaginal layer except that the prostate is shown instead of the vagina

and he says the rectoprostatic fascia is called the rectovaginal and the vesicoprostatic fascia the vesicovaginal. Cunningham (5) also describes the fascia in connection with the female pelvis as the endopelvic fascia and divides it into an upper portion attached to the upper parts of the vagina and cervix and in front of these passing between the vagina and bladder to reach the mesial plane and lose itself upon the walls of the viscera, while the lower layer is that part of the fascia which follows the levator ani muscles and is inserted into the perineal body. The relation of the viscera to the pelvic fascia is such that the bladder rests on the upper surface of the fascia in front. The vagina owing to the backward and upward direction of its axis passes through the plane of the fascia at an acute angle so that its anterior wall which is facing upward and forward is in relation to the under surface of the fascia at that part upon which the bladder rests. Behind this the fascia passes obliquely across the sides of the vaginal fornices and over the top of them being attached to the cervix, and the posterior vaginal wall being longer than the anterior is continued back so as to pass

Fig. 3. Coronal section through pelvis showing the division of the visceral layer of pelvic fascia into layers in relation to the viscera. Uterus, *b* vagina, rectum, *d* levator ani, *e* obturator internus *f* visceral pelvic fascia, *g* vesicovaginal layer *h* rectovaginal layer *i* rectal layer

through the plane of the fascia behind the cervix. In this way the vagina is almost altogether below the plane of the fascia and has its attachment by fibers to the under surface. At the same time the fascia sends numerous fibers to all parts of the vaginal wall.

The cervix uteri definitely passes through the fascia, the vaginal portion being below the supravaginal portion above the plane of the fascia but owing to the oblique direction of the axis of the uterus running forward there is a greater attachment of the fascia in front of the plane of the broad ligaments than behind so that the vesicovaginal layer practically forms a sling across the pelvis, attached to the sides of the cervix and upon which the uterus lies when antverted the fundus resting upon the upper surface of the bladder.

The other ligaments of the uterus appear to be concerned only in the control of the fundus. The broad ligaments and the round ligaments can have no part in the support of the uterus. The latter with the uterus in anteversion are completely relaxed, the distance from their points of origin and insertion being considerably less than the length of the ligaments. The uterosacral ligaments are more difficult to be definite about. They are situated at a higher level than the pelvic fascia, and from the direction in which they run they would draw the cervix upward and backward. From their nature they do not seem capable of supporting the uterus, and a fact which rather bears this out is that in

cases of prolapse they are found greatly elongated but not ruptured showing that they fail and stretch when the weight of the uterus is thrown upon them. There is no evidence that they are liable to damage in labor and therefore why should they so frequently fail in their function after labor?

Retroversion of the uterus is sometimes stated to be a predisposing cause of prolapse but there is clinical evidence that it is not necessarily the initial stage and from the enormous frequency of cases of retroversion in which there is no prolapse even when the retroversion has existed for a very considerable length of time and particularly in those cases where it occurred after parturition it may be concluded that the position of the uterus has no influence upon the supporting structures and that retroversion in the early stages of prolapse is only a concomitant and not a predisposing cause although it is an ultimate development in all cases.

Although I have stated that damage to the levator ani muscles has no effect upon the support of the uterus they and the fascia have a correlated function. The levator ani form almost as complete a sheet as the fascia across the pelvis and these two sheets together form the pelvic diaphragm. The condition is exactly analogous to the abdominal walls

Fig. 4. Showing the levator ani muscle from the outside. It can be seen how impossible it would be for any laceration extending from the vagina to involve the posterior and higher fibers which support the vaginal fornices and uterine cervix. Lacerations can only involve the fibers which spring from the pubic bone and run backward past the vagina to surround the lower portion of the rectum and be inserted in the perineal body. Coccygeus, *a* ischiial spine, *b* anal fascia, *c* ischiolum cut away *d* vagina, *e* aorticolum cut through, *f* levator ani, *g*

tend out and involve the vaginal fornices. If these are examined it will be found that they nearly always take a curved direction when they reach the fornices so that they partially encircle the cervix. They thus involve the attachment of the fascia to the fornices and cervix in a direction transverse to the fibers of the fascia. The degree of evident laceration is no guide to the extent to which the fascia is involved; the fascia may be extensively lacerated even when the cervix is intact. The result is that the fascial sling across the pelvis is interrupted; the fascial ends being only connected to the viscera by loose connective tissue which stretches before the constant strain from above. The fascia is still there and the detached ends at their normal level, but the uterus is able to pass down between them.

Besides laceration in the region of the vaginal fornices laceration may occur in front of the cervix where the fascia bridges across the anterior fornix and passes between the anterior vaginal wall and the bladder. In which case the bladder protrudes between the edges of the fascia and forms a cystocele. These two varieties of laceration may exist separately or together. When in the region of the lateral fornices alone, there results prolapse of the uterus with consequent inversion of the vaginal fornices, but there is no cystocele. The base of the bladder is still supported and the anterior vaginal wall relatively long. The prolapse is usually partial. When the anterior fascia alone is involved the uterus and vaginal fornices retain their normal position but the bladder prolapses forming a cystocele displacing the free edges of the fascia outward and stretching the anterior vaginal wall. When laceration occurs in the two sites, there is prolapse of the cervix and vaginal fornices as well as a protrusion of the bladder; the uterus comes down and the whole anterior vaginal wall becomes inverted.

These different conditions should be clearly differentiated. They are all the result of laceration of the fascia, but the site of laceration is different. They are analogous to abdominal hernias through scars. The recognized method of curing these hernias is to clear the edges of the fascia and unite them

directly and if this is done it does not matter how the other tissues are dealt with. Exactly the same condition prevails in the cases of prolapse of the uterus and cystocele except that the organs which become displaced have a definite position to which they should be returned, and are attached to the fascia whereas the contents of an abdominal hernia has only to be returned to the abdomen and the sac obliterated.

I believe almost all cases of prolapse and cystocele can be dealt with on these lines. There is no difficulty in reaching the fascia at the sides of the cervix and above the lateral fornices, through an anterior colpotomy incision when the bladder is pushed up from the front of the uterus and well out to the sides so as to clear the fascia above the lateral fornices and by stripping the anterior wall away from the bladder at each side of the vertical incision.

The old operation of anterior colporrhaphy and colpo-perineorrhaphy was most unsatisfactory but occasionally resulted in cures even in pronounced cases. I believe these cures were effected upon the lines suggested above. In taking away the anterior flap of vaginal mucous membrane the incision was made sufficiently far out to reach the pelvic fascia and enough was caught in the sutures to re-construct the pelvic sling.

In the present day operations for prolapse especially the Schauta Wertheim type there is one common feature, the high amputation of the cervix which is done to reduce the size of the cervix and considered essential for success, although it must be admitted that numerous cases have very small atrophic uteri and proportionally small cervical portions. The amputation is done well above the vaginal level and the stump covered by the vaginal flap.

I believe it is absolutely impossible to amputate the cervix as described, without reaching the pelvic fascia, and the curative results are due to the inclusion of the fascia with the vaginal mucous membrane in covering the cervical stump. As for the interposition part of the operation, it only relieves the cystocele and does so by using the uterus to bridge the gap in the pelvic fascia. It has

no part in supporting the cervix and is ineffective in the absence of independent means for doing this. It has the disadvantage that it necessitates future sterility and although this only effect, a small number of cases if they do not agree to it the only alternative is palliative treatment or an operation which will only give relief for a short time. As a result of failure with the Schauta Wertheim operation there has recently been suggested a form of vaginal hysterectomy the author (6) of which says the interposition operation is very efficient in the relief of partial prolapse with extensive cystocele. The best results being obtained in cases under forty years of age it should not be adopted in the third and fourth degrees of prolapse. These cases are to be treated by hysterectomy the broad ligament are to be united in the mid line and the free edges stitched close to the urethrovaginal junction so as to compel the bladder to rest on the broad ligament. In this operation the base of the broad ligament when they are separated from the cervix are firmly united together and thus I believe the part of the operation which really cures the prolapse of the vaginal fornices and without which the elevation of the bladder would have no effect. It is again a reunion of the pelvic fascia which is done without removing the uterus would be really effective in curing the prolapse.

What I wish to emphasize in connection with these operations is that the one common item is plastic work in the region of the lateral fornices and cervix but that the importance of this is not recognized and credit for what is effected by this is given to other parts of the operation which are not essential while many of the unsatisfactory results are due to non appreciation of what is the essential part of the operation in cases of prolapse.

The lines upon which I suggest prolapse and cystocele should be treated were pointed out by Alexandroff ten or more years ago and advocated by Hastings Tweedy (7) but they have not been followed or recognized by the profession with the result that the surgical treatment remains unsatisfactory

and is chiefly upon lines which involve the interference with the function of childbirth and is therefore rendered unattractive for an important class of case—the younger women still in the childbearing period of life and probably desirous of having more children.

CONCLUSIONS

1. Prolapse of the uterus and cystocele are due to damage of the pelvic fascia in the region of the lateral fornices and in front of the cervix.

2. Prolapse of the uterus must be clearly differentiated from cystocele they may exist separately or be combined.

3. Laceration of the perineum and levator ani muscles has a part in the production of prolapse. It allows an increase of cystocele when there is the primary defect.

4. Retroversion of the uterus has no tendency to produce prolapse.

5. Prolapse of the uterus and cystocele are analogous to abdominal hernia through scars due to defective union of the fascia.

6. The cure of the condition can be effected by reuniting the fascial diaphragm across the pelvis.

7. The fascial diaphragm can be repaired without interfering with the function of the uterus or dislocating the bladder.

8. The condition can be treated in exactly the same manner before and after the menopause.

9. Atrophy of the uterus has no influence upon its support.

10. Amputation of the cervix other than the removal of an hypertrophied lacerated vaginal portion is not necessary.

THE TRANSPANCREATIC APPROACH TO THE COMMON BILE-DUCT

TRANSPANCREATIC CHOLEDOCHOTOMY

BY ANTHONY H. HARRIGAN M.D. N. Y.

Assistant Clinician, St. Peter's, Fordham Hospital

THE operative measures available for the removal of calculi from the gall-bladder and the upper part of the common bile-duct in a general way evince technical excellence and have well-defined indications for their employment. On the other hand, the underlying principles and the indications for the removal of gall-stones impacted in the terminal part of the common bile-duct or the papilla of Vater are not clearly understood. This seeming obscurity as to the best method appropriate for the treatment of stone impacted in the terminal part of the common bile-duct is explained partly by the fact that owing to the infrequent performance of these operations the average surgeon has but a minimal experience in this field.

The methods proposed in the standard textbooks for the removal of stones in this region represent mainly the personal experience of individual surgeons. The deductions are not based on statistical analyses of large series of cases collected from many clinics. Any operation proposed for the removal of calculi impacted in the terminal part of the common bile-duct is necessarily intricate and difficult. Technical simplicity is intrinsically impossible owing to the anatomical relations of the structures concerned, for at this point the duodenum, the pancreas and the common bile-duct meet at a common center.

At the risk of being prolix, the writer adds another operation for the removal of calculi impacted in the terminal part of the common bile-duct. By this method calculi can be removed from the terminal part of the common bile-duct by an incision in the head of the pancreas. The operation may be properly termed transpancreatic choledochotomy. An experience occurring to the writer furnished the incentive to this study, the object of which is to establish the practicability of

the operation he employed and to bring it forward into the light of publicity. In order to describe clearly the operation the topographical anatomy of the common bile-duct is briefly reviewed and an outline furnished of the operative methods usually recommended for the removal of calculi impacted in the terminal part of the common bile-duct.

Anatomy of the common bile-duct. Anatomists do not agree in regard to the terminology used in the description of the various segments of the common bile-duct. The division appears artificial and arbitrary. The clinical surgeon has contributed an additional classification on the terms of which express more or less a working knowledge of this region. A great deal of the confusion and obscurity of the terminology exist in regard to the terminal part. This is natural, as many anatomical textbooks fail to state clearly the exact relations of the common bile-duct to the pancreas.

The classification of Testut is generally used. He divides the common bile-duct into four parts, namely the supraduodenal, the retroduodenal, the pancreatic and the intraparietal. The use of the first two terms has been criticized by D'Este on the ground of inaccuracy. He maintains that the common bile-duct is never superior to the first part of the duodenum and that therefore the term supraduodenal is a misnomer. This is mentioned in passing but the soundness of the criticism is not considered as the main theme concerns the lower part of the duct. The common bile-duct measures 6.5 to 8 cm. in length. The supraduodenal part is almost 3 cm. long. It is intimately related to the structures contained in the foramen of Winslow and to those leaving and entering the transverse fissure of the liver that is, the hepatic artery, the portal vein, and the lymphatic vessels. At the level of

the foramen of Winslow the common duct occupies the free border of the gastrohepatic omentum. At this point the hepatic artery is but one to two millimeter distant from the left border of the common bile duct. Occasionally the artery divides prematurely, remaining at first quite distant from the common bile-duct, ultimately crossing the hepatic duct obliquely. While other anomalies occur the hepatic artery is easily avoided during operation on the common bile duct.

The closer relation of the first part of the common bile-duct concerns its anterior part. The chief relation is with the portal vein. The common bile duct is situated in a plane anterior to the portal vein. One lymphatic node is constantly behind the foramen of Winslow and lower down one or two nodes regularly separate the common bile duct from the hepatic artery.

The second retro-duodenal part of the common bile-duct measures 0.5 to 1 mm in length. In front of the duodenum while posteriorly are the inferior vena cava and the kidneys.

Testut applies the term pancreatocolic to that part of the common bile-duct which extends from the inferior border of the first part of the duodenum to the point where the duct penetrates the wall of the duodenum. It is synonymous with the intra-duodenal part of other authors. It measures 0.5 to 1 mm in length. It relation have been accurately studied by Quenu who states that it traverses a quadrilateral whose border are limited above by the inferior border of the first part of the duodenum, below by the superior border of the third part of the duodenum, externally by the inner border of the second part and internally by the superior mesenteric vein. According to Testut the course of this portion of the duct may be indicated by an oblique line starting from the inner one third of the inferior border of the first part of the duodenum and ending at the middle of the internal border of the second part of the duodenum. This anatomical quadrilateral of Quenu plays an important part in the operation to be described—trans-pancreatic choledochotomy. It contains the pancreatic portion of the common bile-duct

and its boundaries should be definitely outlined to locate this portion of the common duct. It serves as a guide. In the quadrilateral space described by Quenu as one approaches the duodenum the thickness of pancreatic tissue in front of the common bile duct diminishes from above downward. At the inferior border of the first part of the duodenum it increases to uncover a layer 14 to 15 mm thick in order to reach the common bile-duct. At the middle of this space square the pancreatic duct measures 0.5 mm and at the border of the second part of the duodenum is more than 1 mm. Behind the inferior vena cava and in front of the head of the pancreas, high in turn covered by the branches of the superior and inferior pancreaticoduodenal arteries and by the posterior peritoneal peritoneum.

The intrapancreatic part of the duct which lies within the wall of the duodenum, it penetrates the intestine at the point where the posterior surface becomes the lateral. It passes obliquely through the muscular wall finally in conjunction with the duct of Wirsung in the ampulla of Vater. The base of this small mesenteric cavity is directed upward and to the left. A small transverse slit in the firm transparent one ductal penning in the other.

The diameter of the ampulla measures 6 to 8 mm. The base corresponds in size to the collective extent of the sinces of the two anal the umbilical narrowing considerably and ends in a small opening round or elliptical in shape which seen from the free side of the intestine appears as a tubercle. This forms the caruncula major of Santorini or the papilla of Vater. A smaller projection exists above the caruncula major of Santorini which indicates the duodenal termination of the accessory duct of the pancreas—the duct of Santorini. According to Corning the arrangement of the termination is related is subject to many variations though the above description applies in the majority of the cases. Corning states that the part described by Testut as the pancreatocolic is completely enclosed in pancreatic tissue in 50 per cent of all common bile-ducts.

The term juxta-terminal is applied to

the lower part of the pancreatic segment in conjunction with the intraparietal part by D'Este who states that the expression has a surgical value as it indicates the most frequent site of calculi in this region. He insists that these two sections should be combined and considered as an anatomical entity.

OPERATIVE METHODS EMPLOYED FOR THE REMOVAL OF IMPACTED STONES IN THE COMMON BILE DUCT

In general, an endeavor is made to push the stone into the supraduodenal part where it may be removed through a small vertical incision. If the stone is adherent, usually to the mucous membrane a pair of forceps may be introduced to free it. Irrigation is of doubtful value, though it may aid in the removal of small stones. Massage or manipulation is better but one must be careful not to crush the stone as the small fragments may remain as nuclei for secondary calculi. This operation, called choledochotripsy was first done by Courvoisier. It is indicated in soft cholesterol stones. A major objection is the possible persistence of the detritus to form nuclei of secondary calculi.

When manipulation, irrigation, and massage fail, which is seldom, a direct attack is imperative. The question now arises as to which anatomical approach is best.

The exposure of the common bile-duct where it lies behind the duodenum, by mobilization of the duodenum as suggested by Kocher is of great utility and has many advantages. The technique employed to accomplish this operation has been formulated clearly by Kocher who emphasizes the anatomical importance of the posterior parietal peritoneum which passes from the duodenum to the anterior face of the kidney forming ultimately the upper layer of the transverse mesocolon. In freeing the duodenum the duct is carried with it. It is plainly exposed, and may be directly palpated. When the duct is incised the operation is called retro-duodenal choledochotomy. It is doubtful whether direct incision is of value. In emaciated patients, the continuous loss of so much bile to the body through external drain-

age is objectionable. This opinion is held by Kocher and Lennander who believe that in these cases the bile should be left, if possible to drain into the intestine. Again, injury to the duct of Wirsung is possible, as has occurred at the hands of Kocher and Kraske. Berg alters the technique by draining the hepatic duct. The incision in the common duct may then be sutured. The possibility of retroperitoneal suppuration is an additional argument against incision into the duct in this region.

The chief value of the operation of mobilization of the duodenum is that the stone may be dislodged and pushed up into the supraduodenal part where removal is easily effected. Riedel, Pavr, Lorenz and Berg state that the stone can be displaced in the majority of the cases. However Kocher and Kehr agree that this is occasionally impossible owing to the existence of a pericholedochitis or to the encirclement of the common bile-duct by pancreatic tissue.

The transduodenal operation was first performed by McBurney and soon repeated by Czerny and Mayo Robson. Kocher states that this is the best operation for an impacted stone in the ampulla. He recommends mobilization as an aid in the operation. The duodenum should be opened transversely as there is less likelihood of wounding the blood vessels and the resulting wound is easier to suture. The papilla may be cut, though often simple tearing or expressing is sufficient. The duodenum is sutured in the usual fashion.

That another operative method exists for the removal of impacted calculi in the ampulla of Vater is not widely known. This route is through the head of the pancreas. The writer has performed this in one instance where the pathologic and anatomic conditions prevented the use of other measures. The choice of this method was entirely fortuitous, as he was unaware at the time of any previous work on the subject. Although limited to a single case, his personal experience demonstrates that it is feasible to remove calculi from the ampulla of Vater by direct attack through the head of the pancreas. The patient presented every complication tending

to make difficult any abdominal operative procedure that is a large fatty pendulous abdomen extreme distention of the intestines and a marked depth to the wound. The brief survival of the patient naturally eliminates from the discussion in this particular instance the possibility of objectionable sequelae as pancreatic and duodenal inflammation or fistula. It is indeed regrettable that the clinical test is lacking. However, the pathologic investigation obtained is of value in showing the absence of any injury to the duct of Wirsung.

To illustrate the operation the following case is reported. The patient was admitted to the second surgical division of Fordham Hospital in the service of Dr. W. P. Healy through whose courtesy the writer operated on and reported this case.

Irene N., married, age 46, Russian, admitted November 8, 1914. One day ago she was attacked by this pain in the abdomen vomited several times and the abdomen became markedly distended. The patient was somewhat turgid and apparently extremely toxic. The face was somewhat cyanotic. The tongue was coated. The heart sounds were distant though no murmurs were heard. Examination of the lungs was negative. The abdomen was tremendously distended. The abdominal wall was very thick with fat. There was slight rigidity and tenderness in the upper right quadrant. The abdomen was tympanitic throughout. Temperature 102.3.5 pulse 130 respiration 30. Leucocytosis 23,000. 83 per cent polymorphonuclears.

The lesion was recognized as existing in the upper abdomen. Acute pancreatitis was decided upon as the most likely diagnosis owing to the existence of the extreme distention coupled with the peculiar cyanotic appearance of the face. These two symptoms we have noted occurring fairly often in a case of pancreatitis. Immediate operation was decided upon.

Operation. Ether narcosis. The intestines were tremendously distended. A systematic exploration showed that the liver was enlarged but no abscess was present. There was a moderate amount of brownish fluid in the right flank. The omentum presented a chewed up appearance characteristic of fat necrosis. The pancreas was greatly swollen and enlarged. The gall bladder was tense. It was opened and five stones were removed from the cystic duct. Palpation through the duodenum disclosed a calculus situated in the terminal part of the common bile duct. All efforts to displace it up into the supraduodenal part failed. Owing to the obesity mobilization of the duodenum was im-

possible. No effort to incise the posterior peritoneum could be made with success or safety. Also the depth from the margin of the wound to the duodenum was so great and the distention so marked that I desisted from opening it. As I held the duodenum forward on my finger I indirectly lifted up the pancreas. The idea came to reach the stone through the pancreas. A small nick was made in the pancreas and I quickly came upon the stone. I incised the duct wall and was about to grasp the stone when the supporting hand exerting unlucres-sure caused it to slip under the duodenum to the left. However two more stones lying immediately above appeared in the wound and were easily removed. These had undoubtedly been lying along the papilla.

A rubber drainage tube was placed in the gall bladder according to the inversion method. A cigarette drain was put in Morrison's space while a third reached to the site of the pancreatic incision. The incision was closed up to the point of exit of the drains.

Following the operation the pulse increased in frequency and became exceedingly feeble despite vigorous stimulation. Death occurred twelve hours after operation.

A partial autopsy was permitted at which the duodenum and pancreas were removed *in toto*. The specimen was examined by Dr. Charles V. Carosi, pathologist to Fordham Hospital who reports as follows:

Description of specimen. The specimen consists of the head of the pancreas to which the second part of the duodenum is attached. The duodenum was opened; the papilla appeared to be very much enlarged and the tissues around it infiltrated and necrotic.

The common bile duct presents behind the pancreas. It is greatly distended being 6 mm. in diameter. A probe passed through this emerges without difficulty into the duodenum. The duct of Wirsung appears to be patent.

The pancreas itself is of large size and firm with an occasional area of hemorrhage. Section was taken of the papilla and of the hemorrhagic areas and non-hemorrhagic areas of the pancreas.

Microscopical findings. The duodenal mucosa is necrotic. The epithelium of Brunner's glands is largely desquamated. The peritoneum is richly infiltrated with polymorphonuclear leucocytes. The surrounding lymph nodes are infiltrated with polymorphonuclear leucocytes. The common duct shows only edema of its walls and desquamation of its lining cells. In the pancreas one finds first a few areas of cystic dilatation of ducts and around each the seat of a very active desquamation. A cross section of one duct presents an occluding mass of highly refractile bile-stained material. Other ducts are crowded with necrotic cells, polymorphonuclear leucocytes and bacterial colonies.

There are wide areas of pancreatic tissue in which all semblance of acinar arrangement is ob-

scured, hazy consisting of masses of acinar cells in all stages of degeneration in these areas there is no infiltration. In still other areas there are circumscribed foci of polymorphonuclear infiltration which have not as yet undergone liquefaction necrosis. In some of these foci bacterial colonies appear. There are a few areas of fat necrosis. The whole section presents evidence of moderate fibrosis.

Diagnosis Suppurative pancreatitis, probably following a catarrhal inflammation, because of obstruction of ducts, the bacterial invasion coming from the duodenum via the duct. Such an occurrence is rendered probable by the finding of bile stained material within the small ducts of the pancreas.

Conclusion This operation demonstrated that it is feasible to remove calculi from the ampulla of Vater by direct attack through the head of the pancreas. An investigation of the literature was undertaken to discover if this particular operation had ever been performed before. It was found that the operation had been performed by Tansini, Terrier and MacGraw in order mentioned chronologically making a total of 3 cases. In all these the operation was employed as a method necessitated by the peculiar anatomic or pathologic conditions existing at the time. The three cases are detailed here for the sake of completeness. Kehr states that Keen successfully reached and extracted calculi through the head of the pancreas. A search of the literature fails to find this reference.

Stefan's case reported by D. Esté. The patient was a woman presenting the classical symptoms of stone in the common duct. An oblique incision was made, parallel to the right costal border. Very dense adhesions existed between the hepatic flexure, the great omentum, the superior angle of the duodenum, and the margin of the liver. The exploration proved difficult. After separating the adhesions at the edge of the liver the gall-bladder was isolated and a calculus removed. Catheterization of the biliary duct was impossible. No guide or probe could be passed. The gall bladder was removed. An effort was made to free the common bile-duct at the level of the foramen of Winslow. The reporter states that Stefan discussed with the students present in the amphitheater the advisability of retroduodenal exposure of the bile-duct, but ultimately decided that it was impossible of execution. The reason is not stated but probably the adhesions prevented. On the same ground most likely he did not employ a duodenotomy. In the angle between the superior mesenteric vein, the head

of the pancreas, and the duodenum, the operator felt an abnormal resistance, deeply situated. Grasping the pancreas with forceps and lifting it up he discovered that the pancreas presented the signs of chronic inflammation with sclerotic changes. An incision was made over this mass. The common bile duct was isolated. It was dilated and at the point of entrance into the duodenum was a swelling within the lumen. An incision was made into the common bile-duct at the site of the calculus, which incision involved slightly the outer coat of the duodenum. The inferior pole of the calculus lay in the intraparietal portion of the common bile-duct. Sutures were introduced before the removal of the stone which was firmly adherent to the wall of the duct. Some turbid bile followed the removal of the stone. Retrograde catheterization failed to disclose the existence of additional calculi. Lembert sutures were applied to that portion of the duodenum involved in the incision. Double drainage was instituted. One tube was placed in the cystic duct a second in the common bile-duct and the third passed down to the bed of operation. The wound was then closed. The drainage was excellent. The cystic duct fistula closed rapidly. The common bile duct fistula took a long while to heal, though ultimately complete closure occurred. The patient made complete recovery.

Terrier's case Biliary lithiasis cirrhosis hepatoduodenotomy death. The patient was a man 32 years of age. Vertical incision about ten inches along margin of abdominal rectus, on right side exposure of peritoneum. The transverse colon which was adherent to the lower surface of the liver was detached and turned down but the gall-bladder could not be found. Imbedded in the head of the pancreas, a stone could be distinctly felt evidently in the choledochus. Unsuccessful attempts were made to crush this calculus and to push it toward the intestine. Placing the fingers of the left hand a little behind and below the head of the pancreas, the operator cut down directly upon the calculus and opened the choledochus. The stone was then removed. It was roughened, of oval shape 1½ inches long and ½ inch wide. Catheterization of the choledochus served to show its permeability. The canal above and below the incision which had been applied for the withdrawal of the calculus. Suture of duct. Large drainage tube under the lower surface of the liver near the hilus. Operation lasted about one hour and a half. Death on second day following the operation. Autopsy showed that the incised ampulla of Vater was completely closed by the sutures. The duct which extended from the pancreatic incision to the abdominal wound contained a little blood stained fluid.

MacGraw's case The patient was a woman, 36 years old. The chief complaint was jaundice of five months duration, associated with abdominal pain. A right rectus incision showed an enlarged liver. There were no stones in the gall-bladder cystic or common ducts. A large hard tumor was

felt in the head of the pancreas. The pancreas was incised carefully and deliberately the common bile-duct was exposed opened and the gall stones easily expressed. The pancreas substance at the side of the incision was $1\frac{1}{2}$ inch in thickness and relatively vascular. There was only a moderate flow of bile. The stone was round and measured 2 inches in circumference. The pancreatic wound and the common bile-duct were sutured with kangaroo tendon. A rubber drainage tube was inserted and the wound was partially closed. Recovery.

In order to determine the usefulness and practicability of this transpancreatic approach to the common bile duct the author reproduced the operation in the anatomical laboratory of Fordham University Medical School.

In a male cadaver the supraduodenal part of the common bile-duct was incised and two leaden shots introduced and pushed down to the end of the common duct in order to simulate the operative findings. The quadrilateral described by Quénu was easily recognized. The second and third finger of the left hand were placed behind the second part of the duodenum while in front the thumb of the left hand acted as the palpating finger. The shot could be easily felt. By flexion of the second and third fingers and an upward pull the *entire anatomic mass* lying upon these two fingers was lifted up and brought forward. This rendered the pancreas quite accessible. The pseudocalculi were again palpated and with the pancreas parenchyma lying over them were brought forward. A pair of blunt pointed scissors tore through or dilacerated the pancreas and exposed the terminal part of the common bile-duct immediately before its junction with the duct of Wirsung. The common bile-duct was then nicked longitudinally and the shot exposed. They were easily expressed. The common bile-duct was recognized by the dark color it presented in contradistinction to the white pancreatic tissue. The technique proved simple and this particular cadaver demonstrated the feasibility of removing a leaden shot from the terminal part of the common duct by incising its wall through a preliminary incision in the head of the pancreas without injuring the duct of Wirsung. Following the

operation the duodenum and pancreas and the common bile-duct were removed *in toto*. A careful dissection subsequently showed that the duct of Wirsung was patent intact and uninjured.

The occurrence of injury to the canal of Wirsung during pancreatic operations causing troublesome lithiasis is probably extremely exaggerated. La Courte and Charbonnel collected sixteen cases of pancreatic lithiasis which had been subjected to operation. There were three immediate death following exploratory incision and two deaths occurring within a few days. Allen's patient died at the end of the fifth day. Two pancreatic calculi were removed from a pancreatic cyst situated between the liver and the stomach. In Pearce Gould's case death occurred on the eleventh day. A stone had been removed from the canal of Wirsung. Autopsy showed multiple calculi in the pancreas associated with a hydatid cyst of the liver. In the remaining cases subjected to operation which recovered no mention whatsoever is made of the occurrence of pancreatic lithiasis.

In passing it may be mentioned that Cherecellis has performed experimental suture of the duct of Wirsung. It is a feasible operation. However from a study of the above cases of pancreatic lithiasis there is slight occasion for fear of the development of troublesome complications if the duct be accidentally divided. As to the possibility of injury to the duct of Santorini very little is known.

The lesser duct lies as a rule on a plane central to the main duct. As to the result of its division the writer is unacquainted with any clinical or experimental reports which would throw light upon the question. It is extremely probable that its division accidental or deliberate would be negligible.

The anatomical researches of Baldwin afford valuable information in this respect. He found that in 13.2 per cent of the cadavers (10 out of 76 specimens) the accessory duct failed to join the main duct in 86.8 per cent of the cases (the remaining 66 specimens) junction was effected with the main duct in the head of the gland close to the neck. We see therefore that in 86.6 per cent of the

cases the accessory duct has two terminations. It seems natural to conclude that the division of its duct in any part of its course would not lead to either obstruction or leakage of the pancreatic secretion. The occurrence of hemorrhage might be claimed as an objection to the employment of the transpancreatic route. In the cases of pancreatic calculi, this objection does not exist, for it has been shown by LaCoutre and Czerny that pancreatic stones tend to exteriorize themselves and push back the pancreatic tissue so that the covering layer becomes quite thick and relatively anemic. It is possible that this process takes place in the case of biliary calculi. The investigations of Quénu mentioned above, as to the relative thickness of the pancreatic tissue situated in front of the common bile-duct should be kept in mind. This pancreatic crust is so thin that it would appear that no extreme amount of pressure is needed to make it relatively anemic. Moreover the writer's personal operative experience did not demonstrate the occurrence of hemorrhage, and the cases of Tansini, Terrier and MacGraw do not lend any support to those who would object to this operation on the ground of troublesome hemorrhage.

It should be recalled that an incision of the pancreas in this particular region has been warmly recommended by Vautrin for the treatment of chronic pancreatitis. He advocates the division of the collar of pancreatic tissue which compresses the common bile-duct. This operation has been employed by Vautrin, Martino and Czerny. No mention is made by Vautrin of these surgeons meeting hemorrhage in performing this type of pancreatotomy.

These three objections, injury to the duct of Wirsung, pancreatic fistula, and the occurrence of severe hemorrhage seem to lose in strength when the anatomy of the pancreas and the clinical reports of pancreatic operations are carefully studied. That these objections are real, no one can doubt. That they are valid, is open to question. Nevertheless, these objections are sufficiently real and strong to prevent the selection of the transpancreatic route for impacted calculi,

when the retroduodenal or transduodenal routes are available. However if these routes are impracticable owing to complications, such as occurred in the writer's case and in the cases of Terrier, Tansini, and MacGraw where the adhesions were extensive the operation of transpancreatic choledochotomy has a definite field of usefulness.

The advice of a surgeon in regard to a technical procedure naturally rests ultimately upon the great familiarity of the surgeon with that particular operation. Many operations can be based on *a priori* anatomical, technical and physiological grounds, and the real test is a definite practical experience on the living. For example the extreme intestinal distention of acute pancreatitis may render a certain operation impossible or on the other hand, in a thin, wasted, and emaciated patient, with collapsed intestines, the technical difficulties are diminished.

If one were certain of the calculus being lodged in the lower portion of the pancreatic part of the common bile duct, an incision directly backward into the pancreas might be indicated. If the calculus were partly in the intraparietal part of the common bile-duct, the stone could be reached by an oblique route through the head of the pancreas, approaching the upper part of the calculus so as to come upon it from above downward thereby guarding against injury to the duct of Wirsung.

It may be difficult to determine whether a part of the calculus rests in the common duct or whether it lies completely within the wall of the duodenum. The danger of leakage from the intestine seems remote so long as the papilla is intact. The opening through which the stone is removed is exceedingly small.

The operation of transpancreatic choledochotomy is presented for consideration as a measure of occasional applicability and usefulness. The writer has no intention to urge or even to suggest that this operation be used to supplant the older procedures now in vogue.

EXCISION VERSUS GASTRO-ENTEROSTOMY

By VAN BUREN KNOTT M.D. St. City Iowa

SURGEONS of experience have long since recognized the value of gastro-enterostomy in the treatment of gastric and duodenal ulcer. When the indications for its performance are present and when done by competent hands the results following this operation have justified the confidence with which it has been so frequently employed. It must be admitted however that like many other surgical procedures which have been popularized by competent men it has been too frequently employed when sufficient indications for such employment did not exist.

It is a well established fact that a gastro-enterostomy made in the absence of well defined and understood pathological conditions involving the stomach or duodenum or both will prove worse than disappointing. Yet far too many operations are being performed by surgeons who open the abdomen expecting to find an ulcer and who failing to find one can think of nothing else to do than the gastro-enterostomy which they had decided one or two days before was the procedure necessary in that particular instance. The value of any surgical procedure cannot be determined by men not qualified or by the recital of experiences in which such procedure is clearly contra indicated.

Therefore we may assume that it has been the abuse of gastro-enterostomy rather than its proper and rational application which has brought it more or less into disfavor.

It is with full appreciation of the value of gastro-enterostomy when properly employed that I protest against its employment in every case of ulcer treated surgically.

Statistics now available from many large clinics prove most conclusively that in approx-

imately 70 per cent of patients afflicted with cancer of the stomach it is implanted upon an old ulcer base. It is recognized that the tissue changes which accompany chronic gastric or duodenal ulcer are more or less permanent and potentially cancerous. Rodman recognizing this years ago recommended that where the pyloric region was the seat of an ulcer or ulcers which presented much thickening or other evidences of malignancy a pylorotomy be performed and this principle for ulcers so located has been more or less generally recognized and employed.

It would appear however from a perusal of literature pertaining to gastric surgery and from impressions gained in attendance at various clinics that ulcers situated in other regions of the stomach than the pylorus are not excised as frequently as they should be. With the tendency to cancer development upon an ulcer base regardless of its location in the stomach wall the duty of the surgeon toward these patients is clear.

Ulcers so situated as to permit excision without particularly increasing the immediate risk of the operation should be excised. Moynihan (1) states that in reviewing his early work when gastro-enterostomy alone was employed in the surgical treatment of ulcer about one third of the number of patients only could be pronounced 'cured'. Another third after a varying period of freedom from symptoms had to submit to a second operation in which a pylorotomy or excision of the ulcer was rendered necessary after which they experienced lasting relief. The remaining third developed carcinoma of the stomach from two to five years later.

His experience which parallels that of many other surgeons furnishes additional reason

for the more radical treatment of ulcer at the primary operation. The fact that one third of the number of patients with gastric ulcer who have been treated by gastro-enterostomy alone by a master of gastric surgery require a second operation for the removal of the ulcer before obtaining complete relief from distressing symptoms, should command our earnest attention.

Because of the rich blood supply and thickness of the stomach walls, the repair of a wound therein is rendered not only extremely easy of accomplishment, but practically certain as to prompt and firm union. Ulcers situated upon the anterior surface of the stomach and not involving the curvatures may be very readily excised and should in practically every instance be so treated.

Ulcers located in the pyloric region upon the anterior wall may as a rule be readily excised and should such excision result in narrowing of the pylorus a gastro-enterostomy should also be made. If several ulcers are present in this region or if the thickening and induration attending one ulcer are extreme a pylorotomy or Rodman operation should be done. Pylorotomy is a somewhat more formidable procedure than simple excision or excision and gastro-enterostomy and should be reserved for those cases where pyloric involvement is general and extensive.

Ulcers involving the lesser curvature may be excised by the method of Moynihan (2) followed by gastro-enterostomy which he states should always be done in such cases following excision because of the resulting stomach deformity. It is surprising what results may be secured by this method in ulcers involving so much tissue on either side of the curvature as would appear at first sight to render their complete removal out of the question. However many ulcers so situated will be encountered whose complete excision is out of the question because of adhesions and extensive involvement of the stomach wall, and in such instances we are forced to be content with gastro-enterostomy.

Ulcers upon the posterior wall of the stomach may be excised if not too adherent,

either by employing the rotation method of Summers (3) or the transgastric method advocated by Chaput (4) Deaver (5) and others. I have employed both of these procedures with much satisfaction and have been surprised and gratified with the ease of their performance in suitable cases. Because of adhesion or inaccessibility not all ulcers of the posterior wall can be excised and a gastro-enterostomy must suffice.

Ulcers high in the cardiac end of the stomach are not amenable to excision nor are they benefited by gastro-enterostomy. Jejunostomy offers the best prospect for relief to patients so afflicted.

When operating for perforation of a gastric or duodenal ulcer excision of the tissue involved in the ulcerative process should be done whenever possible before attempting to close the rent in the stomach wall. This removal of diseased tissue not only facilitates immediate wound repair but also lessens the tendency to recurrence.

Whenever possible after excision of an ulcer or ulcers the suture line should be reinforced by an omental graft or flap as long ago recommended by Senn, as thereby the danger of leakage is reduced to the minimum.

As experience increases it will be found that more and more ulcer bearing tissue may be treated radically by excision even to the point of making when necessary a partial gastrectomy for ulcers so situated as to require the same for their removal.

Gastro-enterostomy may frequently be necessary as a supplementary procedure to excision of ulcers wherever situated and should in such instances never be neglected. Believing that the ulcer of today is the cancer of tomorrow it is urged that in every suitable case the ulcer bearing tissue be removed by whatever means or method is in that particular instance most safe and practical.

THE ADVANTAGE OF SEPARATE SUTURE OF THE MUCOUS MEMBRANE IN GASTRIC SURGERY¹

BY RICHARD A. BARR, M.D., FAC. NATIONALE T. S. I. E.

It has unfortunately been proved to the satisfaction of most observers that simple gastrotomy with its low mortality (15 to 20 per cent) will be definitely curative in less than half the cases of chronic gastric ulcer and in hardly more than two-thirds of the cases of chronic duodenal ulcer that come to operation.

That many ulcers do not yield to medical treatment and yet are permanently and completely cured by surgery (simple or complicated) is a fact firmly established as that gastrotomy is not a cure all. More than this, that properly applied surgery can cure every existing ulcer of this region is a reasonable expectation, though the cure may be effected at a great risk.

Leaving out all consideration of cancer, actual or potential, the cure of ulcer by surgery can only be positively assured by resection or permanent exclusion of the involved area. Drainage and the admission of alkaline secretions into the stomach may give temporary relief of symptom. This may be and often is accomplished by gastrotomy. An opening at the usual site of the posterior gastrotomy does under some conditions (pylorospasm for instance or in case of very large stomach) hasten the emptying of the stomach and does admit the bile and pancreatic juice into the stomach. Animal experiment, X-ray observations and average clinical results all go to prove, however, that to act advantageously a moderate sized artificial opening must be assisted by spasmodic or organic closure of the pylorus. Nature ignores to a greater or less extent the artificial opening unless obstruction exists at the natural one. This is an established fact and many ills besides recrudescence of ulceration result from the presence and disuse of the new opening.

My own idea of the proper way to view a gastrotomy is merely as a new channel for food. This new channel is necessitated

by reason of the fact that (a) traction or operation has caused closure of the pylorus. In other words, it bears somewhat the same relation to the urgency of ulcer of the stomach and duodenum that does mydriasis to the urgency of cancer of the rectum.

To exert its definitely curative influence on an ulcer of the stomach or duodenum, surgery must either remove the ulcer or exclude the area occupied by it not only from the passage of food but even from contact with the acid gastric secretion.

These objects can be accomplished in duodenal ulcer by closure of the pylorus, in pyloric ulcer by pylorotomy or closure on the proximal side in all other by resection of more or less of the stomach including the pylorus in suitable cases. Where the resection does not include the pylorus, it might be wise at least to occlude it for prophylactic purposes. The reasonableness of this would be more assured if we knew the etiology of ulcer more definitely. However, prompt emptying of the stomach and the admission of alkaline secretion are doubtless beneficial (experimental ulcer cannot be produced in the absence of acidity) and these can be assured by gastrotomy when done as an adjunct to pyloric closure.

This statement of the case sounds extreme and yet if we are to do anything definite for non-perforating and non-tenacious ulcer, this is almost the irreducible minimum. Fortunately most ulcers are so situated that closure at or near the pylorus will meet the indication. When pylorotomy or resection elsewhere is required, the surgical risk will not be out of proportion to that of the pathology.

In doing the limited work I have had in stomach surgery I have been torn between the conviction that only radical measures would get result, and the fear of the mortality associated with these radical measures.

The technical difficulties of resection of the

Fig. The posterior surface is freed by blunt dissection with narrow knife handle or similar instrument.

Fig. Showing the ligatures of the mucous membrane about clamp.

stomach are not a negligible matter to the surgeon who does not do stomach operations every day. The satisfactory application of clamps, the thickness of the stomach-wall, and the exposure of the inner surface of the mucous membrane have been among my greatest difficulties in doing the technique as I think it should be done. By splitting the stomach wall so to speak, and using the mucous and submucous coats as one layer and the serous and muscular coats as another I have avoided these difficulties to an appreciable degree. This technique has been used to a greater or less extent by others but I do not believe its advantages have been duly appreciated.

This use of the mucous membrane is most satisfactory in occluding the pylorus. For this purpose an incision is made on the anterior surface of the stomach, or of the duodenum according to conditions. This incision is carried down to the submucosa which in all succeeding description will be included in the term mucous membrane. The incision should be preferably transverse to the long axis of the organ and should extend from border to border.

When the mucous membrane is reached the overlying tissues are removed from its anterior surface for at least an inch, and for as much more as may be desirable. Then the posterior surface is freed by blunt dissection with a narrow knife handle or some similar

instrument (Fig 1). A cylinder of mucous membrane is thus gotten up which is clamped at its center. The mucous membrane is closed just on either side of the clamp by a chain ligature of linen tied in two or more sections as required by the width of the cylinder of mucous membrane (Fig 2). The clamp is then removed and the mucous membrane divided along the groove left by the clamp.

When the length of the cylinder of mucous membrane permits double clamping with incision between the clamps, this should be done as it simplifies suture or ligation of the stump. When double clamping is done, I always prefer suture to ligation and use linen which is put in with two needles just under the clamp after the fashion of a harness stitch (Fig 3).

As the next step of the operation a purse string of catgut or linen is thrown around the base of each stump (Fig 4). This purse string is put in the angle of tissue where the exposed mucous membrane terminates, and it may be placed in the mucous membrane itself but preferably should be in the muscular tissue. The stumps are inverted and the purse string tightened. When the width of the stomach makes a purse string undesirable as may readily happen on the proximal side a continued suture approximating the anterior and posterior walls in the inner surface of the overlying muscular coat will serve the

Fig. 3. Showing method of suturing back of wall to double clamp the gland of mucous membrane.

same purpose. The seromuscular tissues are then closed, the edges of the wound being inverted so as to bring the peritoneum in contact with the muscle of the posterior wall or the edges of the seromuscular wound may be brought together by sutures which also catch the posterior wall.

Instead of inverting long stump of mucous membrane the stumps may be ligated (or preferably sutured) close to their bases and then cut short. This makes the inversion less satisfactory but is necessary when on account of the location of the ulcer the dissection has to be carried across the face of the ulcer leaving possibly an opening in the membrane corresponding to it. Inversion of the stump gives an additional sense of security and yet is probably not of any special value provided the mucous membrane is trimmed short.

When the ulcer is of suitable size and located on the anterior wall it may be surrounded by crescentic incisions running from curvature to curvature down to but not through the mucous membrane and the dissection and ligation of this structure completed as just described (Fig. 5).

It would appear at first glance that an incision in the long axis midway between the border would be most satisfactory but there are several objections to this. First the ulcer would be more difficult to avoid or to include by encircling. Then the closest attachment of the overlying structures to the mucous membrane is found at the borders and here we get the most hemorrhage in separating them. At the extremities of the transverse incision we have immediate access to these

Fig. 4. A ligature suture of the ulcer in the anterior wall and the seromuscular wall.

border and also to the posterior surface of the mucous membrane.

In doing this little operation it will not usually be necessary to ligate the omentum at the upper and lower borders of the viscus but this can be done if hemorrhage is at all troublesome.

The advantage this method of occlusion has over the Biondi method and various other methods with or without dissection of the mucous membrane is that it is more apt to be permanent, and is equally as simple as any except the ligature methods which are least reliable.

The advantage of the procedure over von Eiselsberg's exclusion is that the omentum does not have to be divided and the pylorus does not have to be mobilized. Further than this the cavity of the viscus is not opened up and the inner surface of the mucous membrane is not exposed to the same extent. Closing a seromuscular wound on the anterior surface of the stomach or duodenum is a very much less difficult job than closing the two openings left by division of all tissues.

There is small choice in technical difficulty between unilateral exclusion and Rodman's pylorotomy and between these two procedures I would choose pylorotomy. The only advantage the procedure just described has over pylorotomy is that it is more easily performed and it serves almost the same

Fig. 5 Method of resecting an ulcer of suitable size on the anterior wall.

Fig. 6 Showing technique used in pylororectomy

purpose so far as getting rid of the ulcer and cancer bearing area is concerned for the pyloric mucous membrane is removed. It can be made a submuscular resection of the ulcer and cancer bearing and even of what, according to recent teaching is the acid producing area of mucous membrane.

Should the location and extent of the ulcer at or near the pylorus or the presence of adhesions prevent the use of this technique and yet cicatrization should not have produced an efficient and permanent stenosis, pylororectomy at some later date primary or secondary to the gastrojejunostomy is of course indicated.

In doing pylororectomy the mucous membrane can be handled in much the same way as just described. After the omenta have been tied and you are ready to divide the viscera, with or without clamping the duodenal end of the area to be resected, cut down upon the mucous membrane anteriorly and posteriorly and dissect up a short area of it as already described for pyloric occlusion. Double clamp this mucous membrane cut between the clamps, suture or ligate the distal end (Fig. 6) and then suture the seromuscular structures over this stump inverting the serous coat carefully.

The incision through the stomach at the opposite end of the resected area is handled in the same way (Fig. 6). The mucous membrane is closed by the harness stitch of linen already mentioned which is drawn snug as it

is placed (Fig. 3). The mucous membrane may be sutured close up to its line of reflection from the muscle and cut short, but the overlying structures are more easily and smoothly closed if the mucous membrane is long enough for its suture line not to hold the anterior and posterior stomach walls too rigidly in contact.

I have found this method of closure technically much easier than the ordinary one, and that the line of closure is much smoother and less bulky. Hemorrhage can be accurately and permanently disposed of as you proceed. Rubber-covered clamps may be used for the temporary control of hemorrhage and being used for this purpose alone may be loosened at any time for the detection and control of vessels that would bleed.

In performing gastrojejunostomy I use no clamps except a small Murphy clamp at either end of the proposed incision in the jejunum. It is at times difficult to get room on the stomach for a gastro-enterostomy clamp and once applied the clamps necessitate a blind method of controlling hemorrhage.

In the absence of clamps the viscera are held in contact and supported outside the abdominal wound by sutures which catch a good bite on each organ just beyond the limits of the proposed lines of incision. The incisions are made down to the mucous membrane, and this structure cleared for a space half an inch wide at the center of each in

Fig. 6. Cavity of stomach held open by clamps. mucous membrane until posterior seromuscular suture line is completed in gastrojejunostomy.

cision and tapering to the angles. The posterior cut edges of the seromuscular layer are united by a continued suture the mucous membranes are then incised down the center of the exposed areas the cut edges are united all the way round with a whip-over suture and the seromuscular suture completed anteriorly. Catgut is used throughout. The inner layer of sutures placed in this way is a more simple procedure to accomplish than the usual through and through suture the suture line when complete is more flexible and more readily pushed out of the way for the seromuscular suture to follow. A third line of sutures may be used if desired.

If in doing a primary pylorotomy it is considered desirable to anastomose the cut edge of the stomach into the jejunum after the method of Foley the resection of the stomach is carried out as already described. The union between the stomach and jejunum is made as in ordinary gastrojejunostomy (Figs 7 and 8) except that the cavity of the stomach is kept closed by the clamps on the mucous membrane until the posterior seromuscular suture line is completed (Fig 7) and when these are removed by rubber-covered clamps as ordinarily used.

In the *Journal of the American Medical Association* of September 23, 1915 Dr W. J.

Fig. 8. Posterior seromuscular suture line completed and rubber covered clamps in place.

Mayo described a method of excision of ulcer of the body of the stomach accessible from the serous surface and not extensive enough to demand more radical measure. A seromuscular flap is raised the ulcer ulcerized the opening closed by sutures placed in the mucosubmucous coat and the flap replaced with overlapping. Dr Mayo advises gastrojejunostomy but says that blocking the pylorus has not seemed to have added anything to the operation. He got results without blocking but many of us cannot.

I have been experimenting on dogs with a wire snare for dividing the mucous membrane in gastrojejunostomy after the inner line of sutures has been completed both posteriorly and anteriorly except for the small space required by the snare. The snare has worked very well so far as results in dog are concerned but such a strain is thrown upon the sutures when the tissues are drawn upon during the crushing action of the snare that I have not tried it upon a human subject.

I will say in conclusion that unless you have given the matter special attention you probably have no idea what a tough substantial structure the mucous and submucous coats of the stomach make. The peritoneum and muscle are much more readily divided it is easy to cut down to the submucosa and leave it intact and the overlying structures are readily detached from it.

MELANO-EPITHELIOMA

A REPORT OF SEVEN CASES

B. ALBERT COMPTON BRODERS M.D. AND WILLIAM CARPENTER MACCARTY M.D.
ROCHESTER, MINNESOTA
From the Mayo Clinic

THE variety of synonyms which have been applied to pigmented malignant neoplasmata indicates a lack of uniformity of opinion as to just what these tumors are histogenetically. They have been described as melanosarcomata, melanocarcinomata, melanoblastomata, melanomata, melano-epitheliomata, melanotic sarcomata, and chromatophoromata. The majority of writers utilize the term melanosarcoma which has its basis of usage in the old classifications of neoplasmata. These classifications were founded upon a theoretical conception of the specific origin of tissues in the three embryonic layers. The principal cells of naevi or moles having been thought to have their origin in connective tissue of the skin were therefore mesoblastic and hence their neoplastic derivatives have been called sarcomata.

The conception that the spindle and oval cells which are characteristic of melanotic neoplasmata of the skin are of connective tissue origin is founded upon morphology which

we are rapidly learning is not an accurate criterion for the embryologic origin in any specific embryonic layer. Moreover the direct continuity of the spindle and oval cells with the basal cells of the skin can be readily demonstrated not only in naevi (Fig. 1) but also in melanotic neoplasmata (Figs. 2, 3, 4 and 5).

The cells of the latter condition frequently assume an alveolar arrangement (Figs. 6, 7 and 8) which is very characteristic of epithelial tumors. Such alveolar growths have been called alveolar sarcomata and endotheliomata, the latter term inferring their origin in the lining of vessels. In the authors experience no evidence of vascular structure in connection with the alveolar arrangement has been demonstrable (Fig. 8).

We desire to utilize the term melano-epithelioma for the following reasons:

1. If the old three layer hypothesis for the classification of tumors be adhered to it may be well to remember that the pigment bearing cells of the skin (Fig. 9) and perhaps the choroid (Fig. 10) both of which furnish the source of all of the tumors of this series, have

Fig. (50, 6) A section of mole showing the direct connection between the stratum germinativum and the subepithelial cells which are characteristic of moles.

Fig. 3

Fig. 4

The micrograph shows a part of the epithelium of the skin. The cells are arranged in a regular pattern, and the structure is typical of the epidermis. The cells are small and round, and they are closely packed together. The overall appearance is that of a well-organized tissue.

Fig. 6 (4370) Metastatic growth of left villary glands

their origin in the ectoblastic layer rather than the mesoblastic layer. There still seems to be, however, some doubt as to the exact origin of the pigmented cell of the choroid, some authorities believing that they are a part of the embryonic optic bulb and other considering them a part of the mesoblastic tissue which lies adjacent to the retina (Fig. 10).

2 The downward growth of spindle and oval cells of moles or *naevi* and melanotic neoplasms are in direct continuity with the stratum germinativum of the skin (Figs. 2, 3, 4 and 5).

3 The pigment bearing cells of normal skin and of the downward growths of moles or *naevi* are in the basal layer (stratum germinativum) and not in the subjacent connective tissue (Figs. 2, 3 and 4).

4 In accord with more recent observations of the histogenesis of epithelial neoplasms they arise directly as a proliferation of the germinative or regenerative cells of the parenchyma of organs and not from either the differentiated cell or from cell rests.

The cells of melano-epitheliomata may be oval (Fig. 11a) or spindle (Fig. 11b); all cells do not contain pigment (Fig. 11 a b c).

In our series of 70 cases the condition arose in both flat (Fig. 12) and pedunculated (Fig. 13) pigmented areas of the skin. The local growth may be discovered when there is no apparent invasion of the tissue subjacent to the pigmented naevus (Fig. 14). In the majority of cases, however, there is extension to the subjacent structures (Fig. 15). The growth may occupy a large (Figs. 14 and 16) or small part of the tumors (Fig. 15).

The pathogenicity of this type of neoplasm may be seen to best advantage in the following tables:

1	Average age of patients 40 years	
	Number patients between the ages of 20 and 30 years	
	Number patients between the ages of 30 and 40 years	
	Number patients between the ages of 40 and 50 years	13

The conclusions which may be drawn from the

above-mentioned facts are

1 The so-called melanosisarcoma should

be called properly a melano-epithelioma when

such a condition arises in the skin.

2 The condition arises as a migratory

hyperplasia of the basal (regenerative or

germinative) layer of the skin and invades

the subcutaneous tissues and distant organs

as pigmented and non-pigmented oval spheri

cal or spindle cells all of which cells are fre

quently found in the same specimen or even

in the same microscopic slide.

3 The evolution of such neoplasms in

regenerative cells corresponds to the evolution

of cancer in the skin mammary gland,

prostatic gland and stomach.

4 The alveolar arrangement of cells in

This case possessed melano-epithelioma or melanosisarcoma both

had areas in the choroid

This figure includes the eye case which lived eight years after

operation

this series shows no evidence of any relation to vascular endothelium

5 The condition is one of middle life although it may be found from childhood to old age

6 An attempt at determination of the exact duration of the condition from its onset to a fatal termination has failed in this series.

7 There is no specific region of the skin which seems especially predisposed to the development of melano-epitheliomata unless it is on the lower extremities which in this series form the greatest frequency of location

8 Naevi certainly predispose to the development of the condition

9 Metastasis is usually to the regional lymphatic glands.

10 From an economical or practical standpoint melano-epitheliomata which arise in the skin have a high mortality

11 Melano-epitheliomata or melanosisarcomata arising in the eye have a much better prognosis than melano-epitheliomata arising in the skin

12 From a therapeutic standpoint the pathologic history of melano-epithelioma clearly points to the necessity of an early diagnosis and a radical removal of the primary lesion and regional lymphatic glands.

13 From a prophylactic standpoint pigmented areas of skin, such as warts and naevi should be removed when these are in locations which are or have been subjected to injury

Giant Ureteral Calculus—Anomalous Development of the Genito-Urinary Tract

JOSEPH ABELL, M.D., F.A.C.S., F.R.C.S., F.R.C.P.

THE following two recently observed cases seem to possess sufficient interest to warrant detailed report, the first because of the size of the ureteral calculus which was removed, the second on account of the anomalous development of the genito-urinary tract.

CASE 1. T. E. B., male, white, age 38, occupation linotype operator. Date of admission August 1, 1911. The patient presents a negative personal history of any acute or chronic illness and also of neural infection. He applied to his physician for relief of pain in his back which had then been present for about ten days. He stated that he had felt a dull pain in the left lumbar region at the age of 25 that it had recurred at frequent intervals during the next three or four years, that it then became more irregular. At the age of 25 pain of similar character was felt in the right lumbar region. Since then the attack has appeared in the average of once per month. The pain has never been sufficiently severe to require the administration of an opiate to secure relief and until the present attack had not persisted longer than one or two days. Relief was usually obtained by rest in bed supplemented by a hot bath or the application of a hot water bottle. He also stated that except in the last attack relief from pain was always secured by indulgence in sexual intercourse. Between attacks the urinary frequency was four to five times daily, during an attack once to twice daily. Blood had been noted in the urine on a number of occasions. The present attack of pain began ten days previously and had continued without remission.

Examination. Patient rather thin but well developed and muscular, pulse 100, temperature 100.2, F. heart and lungs normal, right kidney easily palpable, enlarged and quite tender, apparently being a large to a medium-sized grapelust. The left kidney was not palpable and there was no tenderness on that side. The urine was muddy in color and in reaction specific gravity 1020. It contained a marked trace of albumin, occasional blood and pus-cells, calcium oxalate crystals, amorphous phosphates, a moderate number of bacteria.

Cystoscopy revealed a practically normal bladder. The left ureteral orifice was normal in appearance and easily admitted the catheter which was introduced without difficulty into the renal pelvis. The orifice of the right ureter was edematous and two and one-half centimeters from the entrance the catheter encountered an obstruction

implying even the likelihood that it was the result of the sound with the calculus. Urine from the left kidney was obtained by albumin catheterization of the present (left) ureteral orifice. The blood count normal.

Radiograph of the present (left) ureteral calculus in the pelvic portion of a hydronephrotic right ureter, a 1.5 cm. diameter, while the right ureter joined the main duct. Diagnosis: bilateral ureteral calculus with right renal hydronephrosis.

Operation. August 1, 1911. Genito-urinary incision, were made upon both sides, each being enlarged downward by incising the rectus sheath. The peritoneum was displaced medially and the ureters exposed, stripped of their peritoneal covering. Considerable fibroplasia on the right side was found about the right ureter and it was separated with difficulty from the surrounding structure. It was incised at a point corresponding to the brim of the pelvis and the calculus removed by traction. A similar procedure was employed upon the left side, both ureteral incisions being closed by interrupted sutures of gutgut. A large external wound was drained with a small strip of rubber tubing.

The post-operative course was uneventful, the patient returning to his work at the end of the third week. The calculus removed from the right ureter was oblong in shape with a blunt beak or curve at either extremity, it measured 5 cm. in length, 1 cm. in circumference at its largest part and weighed 4 grammes. The left stone was more oval and weighed two grammes. The small calculus was composed of carbonate of calcium, the larger one was phosphatic in character.

The points of interest aside from the size of the calculus are bilateral pelvic ureteral calculi, an absence of colic indicating ureteral descent, the symptom being due to urinary retention with hydro-ureter and hydronephrosis, the possibilities of intra-ureteral calculus, growth on lodged nuclei of renal origin, an absence of bladder frequency or pain with practically normal appearance of mucosa and the fibroplomatous thickening around the pelvic portion of right ureter comparable to the induration observed in the fatty capsule of the kidney in calculous disease of long standing.

Desguin describes a male of 34 who had suffered from paroxysms of abdominal pain

Fig. 1. Calculi, actual size, Case 1. Larger one 5 cm in length 7 cm. in circumference, eight 24 grains.

since his fourth year. The patient was observed in an acute attack, and the diagnosis was between appendicitis and ureteral calculus. Abdominal incision to right of the rectus muscle, right ureteral calculus removed irregularly triangular in shape 26 by 23 mm and weighing 10 grammes.

Baker refers to a male of 24 by whom he was consulted because of supposed prostatic disease which improved under appropriate treatment, although pus in the urine persisted. An attack of ureteral colic two months later was attributed to extension of infection but radiography revealed a concretion just above the vesico-ureteral orifice. A ureteral calculus weighing 94 grains was removed by operation.

Parker performed suprapubic cystotomy and removed a ureteral calculus weighing over three-fourths of an ounce. The patient had complained of no urinary symptoms at any time, the inconvenience suffered being referred entirely to the rectum through which the calculus was originally felt.

Bovée removed an unusually large ureteral calculus by transperitoneal ureterolithotomy. The stone measured 2.75 by 1.75 by 1.15 inches and weighed 1310 grains. It was kidney shaped, one extremity larger than the other, grayish in color with rough surfaces.

Two cases of giant calculi are reported by Buerger. (a) A male of 26 presenting indolent symptoms. Enormous ureteral calculus hydro-ureter, ureteritis, ureteral stenosis, hydronephrosis. Calculus more than four inches in length, with a bulbous extremity pointing downward at level of the spine of the scilum. The shape was sinuous, varying from 6 mm to about 1 cm in diameter.

Fig. 2. Diagram of Case 2 showing large stone filling pelvic portion of right ureter, catheter in left ureter, the stone in pelvic portion of ureter.

(b) A male of 55 urinary symptoms ten years duration. Enormous ureteral calculus hydro-ureter, hydronephrosis. Calculus irregularly ovoid with one pointed extremity measuring 2.125 inches in length by 1.125 inches in width at its superior pole.

Specklin describes a male of 48 from whom an enormous left ureteral calculus was removed. Urinary symptoms of many years duration. Nephrectomy and ureterectomy. Curved or elbow-shaped calculus weighed 51 grammes, 11 cm long from end to end, total length along outer curve 12 cm, knob-like projection in upper portion of middle third. In the literature he was able to find the following ureteral concretion of similar size: Federoff, length 19 cm, weight 52 grammes; Rovsing, length 18 cm, width of a bean; Israel, two cases, (a) length 13 cm, circumference 9 cm, weight 54.4 grammes; (b) length 17 cm, circumference 9 cm; Pozzi, weight 34.5 grammes; Lloyd, length 5.2 inches, circumference 2.4 inches.

In a case recorded by Morris the calculus was nearly six inches in length, in one of Gibbon's cases the stone was half an inch in diameter and nearly round.

CASE. P. G. female, white, age 9. Date of first observation September 3, 1905. The patient had been married three years, but had never

beer pregnant nor had he ever menstruated. There was no history of acute illness until the present. Ten days previously he had an attack of acute pain in the lower abdominal region, relieved by nausea and vomiting. The abdominal examination was indistinct and tender, the temperature varying from 101 to 102. The pulse was 110 to 120. The lesion was regarded by the attending physician as appendicitis. At the end of a week the symptoms had practically subsided and he was discharged.

On September 1 the patient experienced another attack of acute abdominal pain which was also accompanied by nausea and vomiting and he was admitted to the St. Joseph Infirmary. September 3, with a pulse of 120 and temperature 101. Her abdomen was found markedly distended and exquisitely tender, especially over the lower zone. While her figure was typically feminine with well developed mammae and wide pelvis, examination showed absence of the inguinal lymph nodes, the external genitalia were normal in appearance. The urethra admitted the index finger without entering the bladder, pinched with high intensity. Rectal examination revealed an exquisitely tender pelvic mass located high in the left iliac fossa. The urine was sterile, the sediment was a trace of albumin, light sediment with a few red blood cells and rod shaped bacteria. The blood count showed hemoglobin 60 per cent, white cell 10,500 with polymorphonuclear neutrophils 85 per cent.

From the history and the physical findings the most probable explanation of the pelvic mass was thought to be retention of menstrual secretion. Acting upon this hypothesis the abdomen was opened in the median line and the tumor found to be a pelvic kidney situated in front and to the left of the aorta and sacrospinous ligament. Examination of both lumbar regions revealed no evidence of a second kidney. No uterus, tubes, ovaries, nor remnants of the same could be detected. It was evident from the operative findings that the lesion was a pelvis in the single pelvic kidney. The subsequent treatment consisted of the ordinary measures employed in such cases.

Three weeks later catheterized specimens of urine from the ureter and the bladder were found negative upon culture. Radiography after injecting the bladder and kidney with dilargol showed the renal pelvis practically normal in size and shape, with one ureter which was between three and four inches in length. The ureter entered the bladder in the usual situation. No evidence of a right ureteral orifice could be found. A cystogram with the bladder in moderate distention showed that it pressed upon the kidney and that the latter produced a change in the contour evidenced by variation in the normal round outline. The rectum was normal in the right side of the pelvis and after being filled with barium was readily observed in the X-ray plate. Subsequent reports indicate that there has been no recurrence of the pelvis.

Under claim that congenital absence of the kidney is an exceedingly rare anomaly, infantes one case of this character. By various available figures in 1909, utopias the occurrence of congenital single kidney was one in 1,841. Since the publication of Moore's compilation (1908) he had found in the literature 60 cases of single kidney, which in addition to the cases previously collected by Billowitz and Moore made a total of 81. In the personal observation cited the left kidney, renal artery, vein, ureter and suprarenal body were absent. He suggests that unquestionably nephroblastoma is attended with peculiar danger to life in case of single kidney where the ureter is occluded by calculi. It is important to remember that the vesico-ureteral orifice is generally absent on the side of the missing kidney. Cystoscopy should be supplemented by ureteral catheterization where two ureteral orifices exist, since in a small percentage of cases of congenital kidney a rudimentary ureter is present. The importance of a single kidney from a surgical standpoint can scarcely be overemphasized. According to Anders advanced lesion of chronic nephritis were found in thirty-two of the total cases, or 27 per cent, undoubtedly either acute or chronic nephritis in cases of renal agenesis gives a less hopeful outlook than when developing under normal conditions. It is essentially.

Mayo states that single kidney occurs more frequently in males whereas the so-called horseshoe kidney is encountered often in females. Among thirty-six cases of gross renal and ureteral anomalies observed in the Mayo clinic during a period of five years, twelve were of the horseshoe variety and six of the single type.

Thomas reports a case of pelvic kidney in a married woman of 35 diagnosed prior to operation for pelvic disease. The vagina was about an inch in depth and no uterus was discoverable upon palpation. The patient had never menstruated but suffered ovarian pain every two months. A rounded tender mass the size of an orange was detected in the left iliac fossa. There had been frequent attacks of urinary frequency during the last

Fig. 3. Case 2. Well-developed feminine figure, absence of vagina, uterus, tubes, and ovaries; single kidney located in pelvis.

year. The patient complained of abdominal pain, especially on the left side. Cystoscopy showed the urethra and bladder normal. Left ureteral catheter arrested 2.25 inches from bladder; right side apparently normal; urine from both sides practically the same. Radiography after double injection of colloidal silver showed pelvis of hydronephrotic kidney low in left bony pelvis. The ureter was 3.5 to 4.5 inches in length.

Cullen mentions a girl of seventeen who had never menstruated. Inspection revealed absence of the vagina. Rectal examination disclosed a hard irregular mass filling right half of pelvis, thought to be uterus with retained menstrual fluid. Coeliotomy right pelvic kidney, uterus and left kidney absent; prolapse of tubes and ovaries in inguinal regions.

Blissell reports the successful reimplantation of a right pelvic kidney in a female of 41. When observed the patient was about eight months advanced in uterogestation; premature labor was induced, and after some delay an asphyxiated child delivered. One month later the pelvic kidney was reimplanted in its normal situation.

During routine examination of the body of a male of 30 who died of valvular cardiac disease Ward found no trace of the right kidney. The left kidney was twice the ordinary size with normal pelvis and ureter.

At autopsy upon the body of a female of

Fig. 4. P diagram. Kidney in front and to left of sacrum hilum looking internally; concave border external.

38 who died following a protracted debauch Glazebrook found a single right kidney. There were two pelves and a single bifurcated ureter. The left kidney and ureter were absent. The right ureter below the bifurcation was normal in size and communicated with the bladder in the proper situation.

Stengel observed at autopsy a single kidney with two ureters and suggested that the surgeon in such a case after using the catheter might be deceived in thinking there were two kidneys and undertake an operation thus the only kidney might be removed. In fact a case of this character was operated upon by Polk of New York (1882); the pelvic mass removed being the right kidney. The patient lived thirteen days with complete anuria, and at autopsy it was found that this was the only kidney.

Mayer and Nelkin cite a case in which there occurred suprapelvic traumatic rupture of a solitary right kidney. No evidence of the left kidney could be found although there were two ureters opening into the bladder in the normal situations. The patient died

Fig 5 Cystogram showing distention of kidney with normal rounded outline in distention

Fig 6 Sigmoid rectum transverse, right side of pelvis Case 1

thirty six hours after operation. Necropsy revealed congenital absence of left kidney, traumatic rupture of right kidney, retroperitoneal hematoma, acute nephritis, kidney infarcts.

Secher describes the necropsy findings in a child without left kidney or ureter, the suprarenal gland being unusually large, the genital organs were also asymmetrical. He states that while about three hundred cases of single kidney have been reported in the literature of the world, these figures are misleading since distinction between total aplasia and atrophy is not always clear. The kidney was single in 1 of 8150 cadavers examined, ie once in every 1104 cases. According to the records the anomaly occurs twice as frequently in males as in females, and the left kidney is usually missing. The abdominal vessels and genital organs ordinarily display more or less deformity in such cases.

TERATOGENESIS OF A HUMAN ATHORACIC ACEPHALIC ACARDIAC TRIPLET WITH NUMEROUS AGENESES

By H. O. WHITE, M.D. LOS ANGELES, CALIFORNIA

From the Anatomical Laboratory of the College of Physicians and Surgeons, Medical Department of the University of Southern California

IT is with a sense of diffidence and more or less with a consciousness of temerity that I have consented to reopen a subject which has been illuminated by the contributions of the most distinguished members of scientific research. A review of the voluminous literature on this subject could not fail to impress one with the weight which is attached both here and abroad to the opinions of Ballantyne, Schwalbe, Hallfeld, Keith, Thiersch, von Winckel, Frankl, Stockard, and perhaps arouse the thought that the theme is well nigh exhausted. A further and more careful review of the literature on teratology almost convinces one of the futility to contribute with entire originality. In the hope however of eliciting a discussion which in some degree may help to enlighten our present knowledge this contribution is submitted.

To Dr. William F. Smith of Calexico, California, I am grateful for sending to the anatomical laboratory of the above mentioned institution a focus of considerable interest from a teratological standpoint and it, together with my previous investigations, constitutes a preliminary report upon which this communication is based.

The fetus is a female, one of triplets of 6½ months gestation with numerous ageneses, as is evidenced by the accompanying photograph and subsequent dissections. The other two fetuses were males and of normal

development. The monster is nine inches long and bears external evidence of the following aplasia: head, neck, thorax, upper extremities, and marked syndactylism of both lower extremities.

Careful dissection of the fetus disclosed complete acardia, asymmetry of the kidneys, the left almost twice as large as the right, absence of both adrenals, internal genitals, spleen, pancreas, and abdominal aorta. As to the alimentary canal, this was represented by a perpendicular tube in front of the vertebral column, terminating by the anal opening in the normal position.

It is agreed by all that in the human, only one embryo develops at a time, and it is equally agreed that twins are not infrequent. Indeed, even triplets and less frequently quadruplets are developed.

The most logical mode of twin production is due to a simultaneous fertilization of two ova, and also it may be brought about by the separation of a portion of a germ plasma of a fertilized ovum into two parts, development proceeding in each part independently to full maturity as is evidenced by experimentation on the lower animals. It is reasonable therefore, to assume that the latter mode of twin production must take place in the very early stages of development, i. e. before the formation of the blastodermic layers, since at that time the ovum is normally already attached to the uterine wall and enveloped by the decidua capsularis. To my knowledge the literature is silent on the possibility of development of triplets or quadruplets by the separation of a fertilized ovum into three or four parts, and although the result of my experimentation on the amphibian eggs does not yet warrant positive conclusions in this respect yet I entertain hopeful anticipation to be able to report the possibility of such mode of development in the near future.

Fig. Photograph of specimen.

F. D. 1

It is an undoubted fact that the small number of embryos which are always found in the same sex are developed from a single ovum. This statement is also true in the case of triplets. In the manner undoubted that in however, none of the three embryos which had most probably developed from a separate fertilized ovum. Most of the usually from twin or triplet and most frequently a consequence of superovulation is the presence of two or more embryos at different ages in the uterus. In the case of two ova at the same period of ovulation. As a result we find almost always two or more fetuses in various stages of development. Since the mother in this case is except the malformation of the same stage of development I am rather of the opinion that its presence was due to superovulation.

It is difficult however to comprehend the stage at that much development of the monster without admitting that once decided direction proves it an ardia and microscopic section of the tumor discloses the presence of its normal structure. The monster had derived its nourishment through the attachment of its umbilical cord either to a placenta common to the two the fetuses or possibly to one of the placenta peculiar to each normal fetus.

It is agreed by all that abnormal conditions of the uterus are among the causes contributing to retarded development of malformations or even total destruction of the ovum.

F. D. 2

The following is a description of the monster. It is a small, white, fleshy mass, about the size of a walnut, with a head, torso, and limbs. The head is small and round, with a single eye and a small mouth. The torso is large and rounded, with a single arm and a single leg. The limbs are short and thick. The monster is shown in a standing position, with its arms and legs spread out. The drawing is labeled 'F. D. 2' at the bottom.

Again, in the case of I stated that monsters are produced at a very early stage of pregnancy, the possibility suggests itself that the very process of implantation of an ovum in a premenstrual membrane which has already

undergone histological changes may be entirely responsible or at least largely a contributory factor to the causation of arrested development.

That the defect may also be due to primary faulty maturation of the ovum is suggested from the report of Ballantyne quoted by Burnbaum that six deformed foetuses were born consecutively to one mother and all were of the same sex. And further that the malformation was not due to any abnormal conditions of the uterus, foetal membranes, or cord may be reasonably assumed from the state of preservation of the foetus in which, excepting the marked hypertrophy of the lower limbs, no evidences of intra uterine maceration or disintegration could be elicited.

That the enlargement of the lower limbs was due to hypertrophy and not to oedema I am convinced from external observation and macroscopic dissection of the foetus.

The amount of hypertrophy of the limbs since the monster died soon (ten minutes) after birth proves conclusively that it must have been present during intra uterine life.

As to the cause of this marked hypertrophy I venture to advance two main hypotheses first that it is due to a primary developmental hyperplasia, and second that it is a secondary hypertrophy resulting from overexertion. The first at once supposes that the structural precedes the functional abnormality due probably to a simple redundancy of growth. According to the second view the functional precedes and causes the structural anomaly.

It is a well-established fact that hypertrophy from repeated forcible contractions is a property of all muscle tissue voluntary or involuntary and further that tendency to normal hypertrophy is greater in the former than in the latter.

There is no proof to the contrary that hypertrophy may occur *in utero* under the same conditions as it does after birth, and owing to the extreme activity of the processes of nutrition and growth *in utero* it is quite possible that hypertrophy could probably take place more readily and to a greater degree *in utero*.

Again for the proper functioning of all organs perfect harmony of co-ordination is indispensable and a disturbance of co-

ordination of any magnitude is apt to exaggerate exertion. When, however I conjecture what the nature of such disturbance of co-ordination can possibly be, I fear that I am perhaps getting into a region of guessing. However I am tempted to advance the suggestion that it is possibly an intra uterine developmental neurosis. Assuming now as I do assume, that a functional cause is responsible for the hypertrophy of the lower limbs that cause I believe to be a disturbance of normal co-ordination and, although I do not wish to lay too much stress upon this functional cause yet no other adequate scientific suggestion has ever been advanced.

As to the causes of aplasia various scientific opinions are entertained.

Burnbaum is of the opinion that faulty and imperfect development of one-half of a twin blastoderm is the cause of malformations.

Schwalbe on the other hand reasons since it is accepted by all that malformations occur at a very early period of development, and since they may be caused by primary developmental defects as well as secondary degenerations hence special investigations must be undertaken separately for every malformation, and he adds that partial destruction of one germ may be considered as a cause, but he does not suggest how that partial destruction may possibly be brought about.

Von Winckel maintains error of development as a cause which must occur before the development of the circulatory system. Imperfect or arrested segmentation is also suggested as a cause.

F P Mall, quoted by E I Werber holds that faulty implantation of an ovum in the wall of a diseased uterus, together with the inadequate nutrition arising therefrom, is responsible for defective development.

O Hertwig, from his experiments with amphibian eggs, subjecting them to the action of a weak solution of sodium chloride, suggests that monsters in the human may possibly be due to the presence of certain poisons such as alcohol or toxins in the blood of the mother.

C R Stockard in a series of experiments with fish embryos, subjecting them to the

action of different chemical substances proved beyond the shadow of a doubt that not only in the very early stages of development but even in the late stages deformities may be artificially produced and although those deformities are evidently caused only by subjecting the eggs to various chemical substances yet he justly admits that this may not be the sole cause of such defects and that any factor capable of influencing the developmental energy could possibly induce similar results.

E. I. Werber from his very recent researches on the eggs of fish besides corroborating the findings of Stockard suggests the possibility of some products due to pathological conditions of metabolism as a teratogenic cause.

It will be noticed that all agree on malformations occurring during the very early stages of development. While I fully coincide with Schwalbe that for each malformation a special investigation should be undertaken yet I venture to maintain that for monsters like the one discussed in this communication one is forced to admit not only the possibility but a high probability of some factor at an early stage of development to be entirely responsible for the cutting off as it were of the anterior half of the embryonic rudiment.

That mechanical forces are capable of producing marked influences on early or even late developing ova or embryos is evident from the experiments of Lewis who produced typical monsters by mechanically injuring the anterior part of the embryonic shield in the developing egg. And also though not necessarily in every case mechanical influences applied to developing eggs during late stages were equally productive of the same results.

On the other hand, Spemann successfully produced monsters by constricting the segmenting eggs with delicate fibers.

May it not be reasonable to suggest, therefore that some such mechanical cause under favorable circumstances may produce an intra uterine constriction of the ovum in early or late stages of development in the lower mammals and also in the human.

The most frequent variety of human monsters is *holo-acardiac cephalus*.

Taruffi was able to collect 108 cases and Foerster states that *acardiaci* formed 18 per cent of his collected cases. In this class of monsters the entire anterior half of the body above the umbilicus is absent and only rarely are rudiments of the missing structures present.

The morphological appearance alone of such monsters suggests the possibility of an intra uterine factor in the nature of a constriction, to be a responsible cause. That constriction I believe to occur in the amnion at an early stage of development, when the separation of the embryo from the blastoderm takes place in the form of an hour glass contraction and as I have intimated above cutting off the anterior half of the embryo on its disk. I am advancing this as an hypothesis and am inclined to believe that in future I shall be able to substantiate this hypothesis experimentally.

If now we admit the possibility of such constriction the various aplasias in this or any such similar monster are quite apparent and do not require any further elaborations.

Careful dissection of this monster and its funus shows the circulation in no way to differ from the usual manner of distribution of the blood vessels in such monsters as first pointed out by Hempel and quoted by Schwalbe that the blood flows to the *acardiacus* through the umbilical arteries and returns through the umbilical veins. It must be remembered that this abnormal circulation is the product of imperfect development and not the cause.

As to the aplasia of the uterus tubes and ovaries it is well known that the genital glands become the ovaries the cephalic portions of Mueller's ducts become the fallopian tubes, and the caudal portions since they are situated close to one another become eventually confluent into a single tube from the proximal part of which the uterus develops and from the distal the vagina.

From their embryology aplasias or malformations of these organs are easily understood. Thus while malformations of the internal genitals may be the result of partial hindrance from growth of portions of Mueller's ducts symmetrically or asymmetrically aplasia must be due to complete hindrance

from growth of Mueller's ducts or may be entirely undeveloped.

In this monster however since the external genitalia are present, particularly the vagina, it is evident that only the caudal portions of Mueller's ducts participated in the process of development, the cephalic portions disappearing or failing to develop entirely.

To Dr. Albert Soiland I am very grateful for the preparation of the photograph, and to Professor Charles W. Bryson, Dean for his encouragement and facilities afforded to conduct research work.

A CONTRIBUTION TO THE ETIOLOGY OF CANCER OF THE OESOPHAGUS AND STOMACH

By WILLIAM LERCHE, M.D. F.A.C.S., S. P. U., ALBANY

By the ancient Roman physicians the oesophagus was called *gula* or stomachus, by the Greek physicians *oesophagus*. Cancer of the oesophagus was probably first described by Galen in the second century under the name of *carcinosis stomachi*. The Arabian physician Avenzoar (1) 1070 to 1162 had good knowledge of cancer of the oesophagus. He originated the method of feeding through a tube patients suffering with this disease and he also introduced the method of rectal feeding in such cases.

ETIOLOGY

The discussion of the etiology in this paper is devoted particularly to the consideration

of a local predisposing cause, which the writer thinks important. Cancer of the oesophagus was formerly considered a rarity and in French statistics for the Seine Department between 1830 and 1840 only 13 cases were found in 9178 deaths from cancer. In the Wuerzburg statistics by Virchow (2) 1852 to 1855 the oesophagus was not counted among the organs frequently affected by cancer. In 1901 Fellchenfeld (3) on the other hand speaks about the remarkable frequency of cancer of the oesophagus.

HEREDITY

Bainbridge (5) sums up the question of heredity in cancer in general as follows: Heredity has been shown to play a rôle but

not one to cause anxiety. Kraus (4) in discussing cancer of the oesophagus says that heredity plays no important part.

GEOGRAPHICAL DISTRIBUTION

It has been stated that natives of the extremely cold regions and those of the tropics and subtropics are practically immune from cancer. Closer investigation however has shown that cancer is found among the Eskimos as well as in the natives of the tropics and von Hanseemann says that there is no kind of malignant growth among us that does not occur in the natives of the tropics and vice versa.

Trolard (6) during six years practice in the French hospital in Safi, Morocco where there came about 100 patients daily had only seen one case of cancer of the digestive tract (a case of cancer of the liver). He says that it is extremely rare among the Berbers. This has been the experience of others in Egypt and other parts of northern Africa.

In Sutherland's (7) report from Lahore, India, he states that among 43,412 patients admitted to the hospital between 1892 and 1903 there were 2 cases of cancer of the oesophagus and none of the stomach in 329 cases of carcinoma. Sutherland remarks that cancer of the stomach is rare.

Niblock (8) tabulating the records of malignant tumors in Madras General Hospital from 1892 to 1901 found 4,270 cases. Of these 976 were cases of carcinoma of which 21 were of the stomach and 3 of the oesophagus.

On investigation made in the Portuguese colonies (73) a total of 4 cases of cancer of the stomach and 3 cases of cancer of the oesophagus had been recorded in various hospitals some records extending back 13 years.

Cook (9) has seen cancer of the oesophagus among the natives of Uganda, Central Africa.

Maxwell (10) found that in 11,000 patients in Changpoo Hospital in South China there were 54 cases of cancer of which 8 were of the oesophagus (7 males, one female) and 2 of the pylorus.

At the hospital for Chinese in Tartar City, Peking, Foulkes (11) found a fair number of

cases of cancer. He mentions one case of cancer of the oesophagus.

Meldorf (11) has reported cases of cancer of the oesophagus and stomach in the natives of Greenland.

Renner (13) says that in the negroes in Sierra Leone who are aborigines are rather free from cancer there is increase in the cancer rate when they adopt the white man's diet and mode of living. In 453 cases admitted to the hospital from 1870 to 1900 there were 20 cases of malignant growth in 10,163 cases admitted from 1900 to 1909 there were 26 cases. One case out of the 40 was cancer of the oesophagus. No case of cancer of the stomach is mentioned in the report.

In the temperate climate which corresponds to the so-called civilized part of the world cancer is frequent but the statistics show that within this zone the death rate from cancer varies considerably in the various countries. Thus according to Williams (14) Switzerland has the highest cancer rate with 13 deaths per 100,000 living inhabitants and Hungary one of the lowest with 39 deaths per 100,000 living.

The relative frequency with which the various organs are affected by cancer varies in the different countries.

It is sometimes seen that cancer occurs more frequently in certain parts of a country, thus according to Haeblerlin (15) cancer of the stomach was the cause of death in

3 per cent of all deaths in northeast Switzerland, 1.5 to 2 per cent of all deaths in the western half of Switzerland.

1 per cent of all deaths in the southern part of Switzerland.

I have roughly figured out on the basis of

TABLE I.—CANCER OF THE OESOPHAGUS

	Males	Females	Ratio

the statistics of Nencki (16) that cancer of the oesophagus was the cause of death in

- o 7 per cent of all deaths in northeast Switzerland
- o 46 per cent of all deaths in the western part of Switzerland
- o 24 per cent of all deaths in the southern part of Switzerland.

Of all cancers in men, in the District of Wangen (Canton Bern, Switzerland) 36 per cent were of the oesophagus.

Kolb (17) found that in Bavaria cancer of the oesophagus was more frequent in the northern part than in the southern part.

In Normandy France, the rate of cancer of the stomach was very high in the south of France it was very low

SEX

Men are much more liable to cancer of the gullet than women. Table I shows the ratio

of male to female deaths from cancer of the gullet in various mortality statistics and in some collections of cases.

In Table II is shown the percentage of cancer in all deaths, and the percentage of cancer of the oesophagus and stomach in men and women in the post mortem material of various authors.

In Table III is seen the proportion of deaths from cancer of the oesophagus in men and women in the autopsy material of various authors.

In men carcinoma of the stomach is the first in order of frequency in most cancer statistics, and in some statistics cancer of the oesophagus comes second

AGE

Carcinoma of the oesophagus is a disease of middle and old age. It is comparatively rare under the age of forty.

According to Philipp (29) no case has been reported as occurring in childhood, and the youngest cases on record are probably—

Helman case, 9 years old Mampell case 30 years old Stewart case 3 years old Staryanis case, 24 years old.

Table IV shows the age and sex incidence of malignant tumors of the oesophagus and stomach based on the national mortality returns 1901 to 1903 for England and Wales.

Table V shows the age incidence in 30 of the author's clinical cases of cancer of the oesophagus. In each case the diagnosis was made by microscopical examination of specimen removed through the oesophagoscope.

SITE OF CANCER IN THE OESOPHAGUS

Any part of the oesophagus may be the site of cancer as shown in Table VI. The question as to what parts of the organ are most frequently the sites of cancer is apparently as unsettled today as it was in the past century, some authors claiming the upper third, some the middle third and some the lower third. Only on the basis of large statistical material can this question be settled.

In Table VII I have brought together all

TABLE VII — CANCER OF THE OESOPHAGUS. TOTAL NUMBER OF CASES COLLECTED 4020. ARRANGED ACCORDING TO NATIONALITY.

been arranged according to nationality that in the English and French groups the upper end is the part of the oesophagus most frequently involved by cancer while in the other groups the lower part is affected in the majority of cases.

Koenig (54) in 1880 in discussing the question of the relative frequency of the seat of cancer in the upper middle and lower part of the oesophagus and referring to Mackenzie's (31) cases said: 'Can it really be that in England cancer of the oesophagus is so much more frequent in the upper third?'

It has been my experience in oesophageal work that patients who locate their trouble in the upper end of the oesophagus are apt to consult the throat specialist while those who locate their affliction in the lower part of the organ will consult the general practitioner the surgeon the internist, or the stomach specialist hence the latter cases become scattered among a larger number of consultants and are not reported because each one gets only a small number of cases. This observation seems to be borne out here, because if the cases published by the throat specialist are segregated the result is entirely different, as seen in Tables VIII and IX.

Note the striking difference between the groups of Newman, Turner and Rawling and the St. George Hospital, and likewise between Guémez and Lamy. Rawling says that he does not believe that cancer in the upper end of the gullet occurs in more than 10 per cent of cases. It seems reasonable to

assume that if a larger number of autopsy reports from large general hospitals in England and France come forth it is likely that they will show about the same results as those of the other European countries.

Although the number of cases here brought together may not be sufficiently large to settle definitely at what part of the oesophagus cancer most frequently occurs, it is highly probable that Table IX gives the correct answer representing as it does the clinical and post mortem records of large general hospitals and clinics in the various countries.

Assuming, therefore that Table IX gives the true expression the question immediately presents itself: Why does cancer occur more frequently in the lower part of the oesophagus than in the upper? For the sake of comparison I have analyzed 198 cases of cicatricial strictures of the oesophagus caused by swallowing corrosive fluids, and found that 18 per cent occurred in the upper part 29.8 per cent in the middle part and 52 per cent in the lower part of the organ. This corresponds exactly to the seats of predilection of cancer of the oesophagus. The question is whether this is a mere coincidence, or whether there is some definite physiological law that determines these so-called seats of predilection?

In a previous paper (55) I have shown that the relative frequency of the seats of cicatricial strictures of the oesophagus following the ingestion of corrosive fluids increase from above downward for the reason that the speed of the peristaltic wave which propels the oesophageal contents decreases from above downward, thus permitting the corrosive fluid to remain longer in contact with the oesophageal mucosa in the lower parts, with consequent deeper insult. In the lower thoracic part where the content comes to a momentary stop the destruction is usually the most extensive and this part is the most frequent seat of cicatricial strictures. The upper end which is the narrowest part of the oesophagus, and where the peristaltic movement is swiftest, often escapes entirely.

The narrowest part of the oesophagus is at the inlet, and from there to the cardia the lumen increases (with slight constrictions at certain parts) so that the statement found in

most textbooks—that cicatricial strictures as well as cancer of the oesophagus are found at the physiologic constrictions inferring that the latter are responsible for the pathologic conditions mentioned—does not seem to have sufficient foundation. Furthermore in animals we find physiological constrictions and yet in these cancer of that organ is extraordinarily rare.

If we now examine the stomach from a similar viewpoint we find that in regard to the parts of the organ most frequently affected by ingested corrosive fluids it has been observed that when a smaller quantity has been swallowed the effect is most frequently seen along the lesser curvature and in the pyloric region particularly in the latter.

Thus Hoffman (56) describes a specimen of a stomach in which continuous, 3 to 10 mm wide streaks caused by swallowed hydrochloric acid were found along the lesser curvature from the cardia to the pyloric region. In the latter region the area of destruction was most extensive while the rest of the stomach with the exception of a few insignificant scars in the fundus was normal. This corresponds to the findings of Ernest and others.

According to Aschoff (74) lesions from swallowed acids are especially found along the lesser curvature.

It seems apparent therefore that corrosive fluids like other fluids swallowed ordinarily pass from the oesophagus along the lesser curvature of the stomach to the pyloric region where the corrosive fluids remain for some time.

The reason why the fluids pass along the lesser curvature which I have called attention to in a previous paper (68) is that the inner oblique muscular layer of the stomach contracts in such a manner as to bring the cardia and the pyloric part closer together and to make the gastric mucosa form a trough or canal into which the fluids coming from the oesophagus are directed. This canal becomes so to speak a continuation of the oesophagus and although it has already been given various names it seems to me that the designation *gula gastrica* or the gastric gullet would be quite appropriate. The function of this canal has been demonstrated in the dog by Cohnheim and in the horse by Ellenberger.

In experiments on certain animals it has been observed that fluids are spurted into the stomach with considerable force which is likely due to the contraction of the epicardium. If this is also the case in human beings the speed with which the fluid travels would probably be greatest as it emanates from the cardia, and would decrease toward the pyloric region with the same consequences that we have seen in the oesophagus namely that the upper part may escape while in the lower part where the speed is slowest and especially in the pyloric region where the fluid comes to a stop the injury is most extensive when corrosive fluids are taken. The pyloric region is the part of the stomach most frequently and usually most severely affected by the corrosive fluid at times it is the only part affected the rest of the stomach as well as the oesophagus escaping entirely.

Thus in 59 post mortem cases collected by Quenu and Petit (57) in which the stomach was severely damaged from the ingested corrosive fluids causing death the oesophagus was simultaneously affected in 34 of the cases. In 20 cases or 33.89 per cent the oesophagus was not affected. In 34 less severe cases that had been collected by the same authors and that had survived the effect of the poison and had been operated upon for obstruction in the pyloric region caused by the corrosive fluid the oesophagus was simultaneously affected in only 6 of the cases while 28 cases or 82.3 per cent had escaped.

It is of interest to note that in the 59 post mortems in which the effect of the corrosive fluids caused death the duodenum was only affected in 23.8 per cent. In none of the 34 cases of the second group was the duodenum affected.

In cattle similar observations have been made. Lichtenstern (58) found this in the post mortem examination of 5 cows that had to be slaughtered on account of illness following the accidental feeding of hot fluid fodder. The autopsy appearances were the same in all namely changes confined to the omasum or third stomach, while in the rest of the stomach and oesophagus there were no changes except in Cases 1 and 2 where parts of the tongue pharynx and oesophagus were also

found affected. Cases 1 and 2 stood nearest to the end where the fodder was poured into the trough. The function of the oesomus is to dehydrate the food, and fluid foods pass directly into this part.

In regard to the most frequent sites of cancer in the stomach, it may be said to be a repetition of what is true of cancer and cicatricial strictures of the oesophagus, namely, there is an increase from above downward, following what has been referred to as the continuation of the oesophagus, "the gastric gullet." In other words the cardia, the lesser curvature, and the prepyloric part are the regions of the stomach most frequently affected by cancer and Table V shows that this region was affected in 79.5 per cent.

TABLE X.—SHOWING THE SITUATION OF THE TUMORS IN 1,300 CASES OF CANCER OF THE STOMACH COLLECTED BY WELCH (59)

Pyloric region	782	or 60	8 per cent
Lesser curvature	48	or 3	per cent
Cardia	64	or 5	per cent
Prepyloric wall	44	or 3	per cent
Whole or greater part of stomach	61	or 5	per cent
Multiple tumors	1	or 1	per cent
Greater curvature	14	or 1	per cent
Anterior wall	20	or 1	per cent
Posterior wall	9	or 1	per cent

In Table VI, I have collected some more recent groups of autopsy cases, which show the same, namely 78.88 per cent. It will be noticed that in the latter table the percentage of cancers of the pyloric region is somewhat lower and the percentage of cancer of the lesser curvature is somewhat higher than in Table V.

The exact starting point of the growth may be impossible to determine at autopsy, but von Mielecki (27) found in his material of 156 cases of cancer of the stomach that the center of the carcinomata occurring in the pyloric region was several finger breadths away from the pyloric sphincter the latter being usually free.

Clinically according to Mikulicz (62) the lesser curvature near the pylorus is the primary starting point in most cases of cancer ventriculi—probably in 40 per cent, which would correspond to the pyloric vestibule and the pyloric canal.

Von Hacker (50) in 100 cases of cancer of the oesophagus found that the lower part of the organ was affected in 49.62 per cent. Of

these cases 27.49 per cent were found above the hiatus, while only 22.13 per cent were at the cardia.

It would seem then that just above and in the epicardia, and just above and in the pyloric canal, which probably are the parts regulating the evacuation of the oesophagus and stomach respectively are the favorite seats of cicatrices from ingested corrosive fluids, because there the fluids remain the longest in contact with the mucosa. The same parts are also the favorite seats of cancer (Fig 1).

TABLE XI.—SHOWING THE MOST FREQUENT SITE OF THE TUMOR IN 1,735 CASES OF CANCER VENTRICULI EXAMINED AFTER DEATH

SEX

Cancer of the stomach occurs somewhat more frequently in men than in women, but in large statistics the difference is small, thus, in the statistics of Martin (63) of 20,000 cases 58 per cent were men.

AGE

Cancer ventriculi is a disease found most frequently between the ages of 40 and 70. It is comparatively rare before forty and after seventy. A number of cases have been seen in children, and it has been observed in the newborn. (see Table VII)

CANCER OF THE OESOPHAGUS AND STOMACH IN ANIMALS

Investigation has shown that cancer is not a disease confined to man because it has been demonstrated in nearly all species of vertebrates including marine fish living in a state of nature. The Imperial Cancer Research Fund (64) of London, in its reports 1905 makes the statement that the probability is that when the full facts are known the recorded incidence of cancer at all ages will

approximate in cattle and in mice that at all ages in the human subject

The statement in regard to the cattle was apparently founded upon the reports of Veterinary Inspector Trotter who in 190 found 1 cases of malignant new growths in 62 035 cattle of all ages and in 1903 found 131 cases of malignant new growths in 47 362 cattle of all ages slaughtered in Glasgow. Nearly all of the cases were found in old cows imported from Ireland.

The Research Fund also reported 3 specimens of cancer of the stomach in cows examined by them in 1903. On the basis of these reports it has been stated in more recent literature that cancer of the stomach is common in cattle.

In the statistics of Stickers (65) based upon the reports from the Berlin Veterinary school and the Berlin and the Munich Statistic Pathologic Institutes for a period of 22 years together with extensive search of the literature there were

- 8 cases of cancer of the stomach in horses
- 1 case of cancer of the oesophagus in a horse
- 1 case of cancer of the stomach in cattle
- 1 case of cancer of the stomach in a dog

Schmev (66) has recently reported a case of cancer of the stomach in a monkey 8 to 10 years old which corresponds to the age of 40 years in man.

To the United States Bureau of Animal Industry during the months of November and December 1914 and January and February 1915 there had been reported 94 cases of carcinoma and sarcoma in a total of 350 000 cattle killed or 0.004 per cent. There was no information given about the site of the tumors. The number of canners or old cows from the age of 8 to 15 years or older killed amounts roughly estimated to about 25 per cent of the total in some slaughter establishments—probably in all of them.

Not infrequently and for various reasons the viscera are condemned as food products and are disposed of without complete inspection. As such viscera might harbor malignant growths nothing conclusive can be drawn from the above reports. According to the experience of meat inspectors however

Fig. Schematic drawing of the human upper digestive tract showing the esophagus and the stomach and the gastric gullet also the relation frequently with the esophagus and carcinoma structure occur in the various parts of the upper digestive tract.

cancer of the stomach in cattle must be very rare.

In 1904, wild animals under observation in the New York Zoological Park (67) during five years but one case of true neoplasm occurred namely a sarcoma of the ovary in a raccoon dog. Seven hundred forty-four of these animals came to complete autopsy.

With the exception of the one case in a horse mentioned above I have found no report of cancer of the oesophagus in animals in the literature.

SUMMARY

A brief summary of what has been said so far in this paper shows that—

1. Cancer of the oesophagus is exceedingly rare in animal.

2. Cancer of the stomach is rare in animals.

3. Cancer of the oesophagus and stomach is comparatively rare in the natives of the tropical and subtropical countries.

4. Cancer of the oesophagus and stomach is common in certain countries in the temper

ate climate zone, inhabited by so-called civilized man

5 Cancer of the œsophagus is much more frequent in men than in women

6 Cancer of the stomach occurs with almost equal frequency in both sexes.

7 Cicatricial strictures of the œsophagus and the stomach, from swallowed corrosive fluids particularly form at certain parts of those organs and for definite physiological reasons

8 The favorite sites of cancer in the œsophagus and in the stomach correspond exactly to the favorite sites of the cicatricial strictures in those organs.

It seems, then that although any vertebrate organism may be the subject of cancer and that cancer of the œsophagus and stomach may occur in any race civilized man in particular is peculiarly liable to cancer of those organs. Why?

Naturally the food and drink passing into the œsophagus and stomach suggest themselves for investigation, and a great many articles of food and drink—particularly meat and alcohol—have been put down by various writers, as predisposing causes of cancer. The importance of some of these articles has possibly been overestimated on the other hand some authors are inclined to go to the other extreme and disregard food and drink as possible predisposing causes. Mackenzie (31) in 1880 said. Nearly a century and a half ago Van Swieten was disposed to attribute the origin of cancer of the gullet to swallowing very hot fluids, especially coffee which at that time was coming into general use. This view however was no doubt erroneous and was strongly opposed by Morgagni. Perhaps the view of Van Swieten was not erroneous after all.

It is said that the X rays have been responsible for the production of cancer of the skin in some cases and that in the wearers of Kangri baskets in the smokers of short clay pipes, the chronic irritation produced by those habits has been responsible for the growth of cancer

There is a reason why cancer of the œsophagus and the stomach is so common among the inhabitants of certain countries in the temperate climate zone.

There is a definite reason why 79 per cent of all cancers of the stomach occur in the small area comprising the cardia, the lesser curvature and the prepyloric region.

May not chronic irritation caused by the large quantities of hot fluids habitually consumed by civilized man, and the mechanism directing the fluids into the gastric gullet be responsible?

That cicatrices from swallowed corrosive fluids are especially found along the lesser curvature points to the possibility that fluids may have something to do with the fact that most of the tumors of the stomach are found in this very region—the high way of the fluids.

Habitual local application of undue heat, causing chronic irritation, appears to be inductive to malignant changes of the tissues in other parts of the body may not this also be the case in the stomach? If this view is correct it carries with it the conclusion that the hot fluids are also the main predisposing cause of cancer of the œsophagus

When I say hot fluids, I do not mean to the exclusion of hot solid or semi solid food but as these latter are more or less masticated and mixed with saliva, the temperature of such a bolus may be somewhat reduced by the time it reaches the œsophagus and stomach. Furthermore solid food is probably not directed along the lesser curvature to the pyloric part, the area in which the majority of gastric cancers are found

The hot fluid, on the other hand, is quickly swallowed and on entering the œsophagus passes swiftly along the upper part of the organ slower through the lower half and after coming to a momentary stop above the epicardium is propelled into the stomach, where it passes along the gastric gullet, as outlined and comes to a halt in the prepyloric part. As the fluid travels swiftly through the œsophagus its temperature has probably not become much reduced by the time it reaches the highly specialized epithelial lining of the stomach.

The probable relation of the function of the gastric gullet to the pathology of the lesser curvature I have alluded to in a previous paper (34).

Very hot or very cold drinks may be retarded in its passage through the œsophagus for the sphincter cardiacus is liable to be set up by extremes of temperature hence the mucous membrane may be exposed longer than usually.

Fluid like coffee, tea, soups etc. are habitually taken at a temperature that would be unbearable to the kind and the frequent travel of very hot fluids through the œsophagus and along the gastric gullet may have the same effect upon these parts as the heat from the Kangri basket has on the skin of the abdomen of the natives of Kashmir India (69). These people wear a basket containing a small vessel with burning charcoal next to the kind on the abdomen during the cold weather and the chronic irritation from this heat is considered the cause of the epitheliomata of the kind of the lower abdomen and thighs so frequently seen among them.

As mentioned before in this paper men are more liable to cancer of the œsophagus than women—probably about in the proportion of 1 to 1. On the other hand carcinoma of the stomach occurs with almost equal frequency in the sexes although somewhat more frequent in men.

How can this phenomenon be explained?

I think in the difference in the mode of drinking in men and women. While men commonly take large swallows and often drink hurriedly women almost invariably sip fluids and eat and drink more slowly. Consequently in women only a small quantity at the time passes swiftly through the œsophagus. When the hot fluid reaches the stomach however it strikes the highly specialized epithelium of less resistance than that of the œsophagus and coming to a stop in the prepyloric region the benefit of the milder swallow which saves the œsophagus is eliminated and both sexes are practically on the same footing. The epithelial lining of the œsophagus covered as it is with mucus may escape the effect of the heat in a small swiftly moving quantity of fluid while large swallows taken at short intervals do damage by longer exposure.

This is well illustrated by the effect of a small quantity of corrosive fluid swallowed as mentioned earlier in this paper which will often leave the entire œsophagus intact and only attack the lesser curvature and the prepyloric region or the prepyloric region only.

Thus it may be said that the pathology of the lesser curvature indicates that the physio-

logical function of the gastric gullet according to the theory of Retzius is correct. Nevertheless it may be said that the physiological function of the gastric gullet tends to support the hypothesis that fluid causing chronic irritation particularly hot fluid may be responsible for the lesion of this part of the stomach as well as that of the œsophagus.

Judging from the case of Petit and Ouenou the pylorus ordinarily does not permit the immediate passage of a corrosive fluid into the duodenum. In the 5 per cent of the 1st of the first group in which the duodenum was affected the corrosive fluid had probably overwhelmed the pyloric regulating apparatus and paralyzed it to such an extent as to interfere with its normal action.

According to Mueller (1) the temperature of fluids entering the stomach much above or much below the body temperature is quite rapidly modified and the fluids are not permitted to pass into the duodenum until they have attained a temperature approximately that of the body.

The pars pylorica therefore is apparently also an apparatus of protection for the delicate duodenum. The latter organ has the benefit of the protecting and modifying function of the stomach and it receives the contents of that organ in a condition for which it is physiologically adapted thus escaping the chronic irritation to which the œsophagus and stomach are exposed. That this has something to do with the relative freedom from cancer which the duodenum enjoys seems highly probable.

In light of what has just been said it is of interest to compare the cancer statistics of the north and south of Europe taking for examples those of Norway and Italy. The Norwegians are one of the healthiest races in the world according to the death rate during the last decade. The cancer rate however is comparatively high namely 9 per 100 000 population.

Recent statistics by Munch Soegaard (10) show that cancer of the stomach in the rural districts of Norway is 65.3 per cent of all cancers or 70 per 100 000 population.

Cautionately the death rate of cancer of the œsophagus is not mentioned here in the statistics but is not far off.

It is interesting to note that cancer of the female generative organs in the rural districts was only 5.5 per cent of all cancers which is unusually low (see Table VII). It is pointed out by Soegaard that cervical laceration must be frequent, as the peasants usually have large families. On the other hand gonorrheal infection is practically unknown among them.

The cancer rate in Italy is one of the lowest in Europe. It was 52 per 100,000 living inhabitants in 1899 (14). An analysis of the statistics (71) shows that cancer in general is less frequent in the south than in the north of Italy. This is particularly the case with cancer of the gastro-intestinal tract, and especially of the oesophagus and stomach. Cancer of the oesophagus and stomach combined, was 14.5 per 100,000 population. If the north and the south of Italy are considered separately however we find that the nine northern compartments show 19.8 per 100,000 living inhabitants, while the seven southern compartments including Sicily and Sardinia showed only 5.3 per 100,000 population of cancer ventriculi and oesophagi combined, or nearly four times as many in the north as in the south. The death rate from cancer of the female generative organs in Italy was 8 per 100,000 population but of this the north showed 9.8 per 100,000 inhabitants while the south had 5.8 (Table VIII). The difference between the death rate of the north and the south of Italy in cancer of the female generative organs is therefore not nearly so striking as the difference between the north and the south in regard to cancer of the oesophagus and stomach.

The death rate from cancer of the female generative organs in the rural districts of Norway was 6 per 100,000 living inhabitants, which is equal to the lowest in Italy. In other words, while cancer of the stomach in Norway according to the statistics, was several times as frequent as in Italy cancer of the other organs occurred with about equal frequency in both countries. In Norway (72) the consumption of meat and alcohol is low the consumption of coffee is excessively high (12.25 pounds of coffee and 0.12 pounds of tea per head per annum). In Italy (72) the

consumption of coffee and tea is very low (1.61 pounds of coffee and 0.005 pounds of tea per head per annum). The climate of southern Italy is nearly tropical.

In the Norwegian rural districts hot coffee in large quantities, is taken four to five times a day. The same is said to be the custom in the northeast part of Switzerland, and in certain parts of the latter country hot coffee with brandy is said to be a favorite drink.

TABLE XII.—RURAL DISTRICTS OF NORWAY

Cancer of the stomach per 100,000 population	70
Percentage	4
Cancer of the female generative organs	5
Percentage	1.5

TABLE XIII.—ITALY

Cancer of the oesophagus and stomach per 100,000 population—	
Italy	14.5
North Italy	19.8
South Italy	5.3
Cancer of the female generative organs per 100,000 population—	
Italy	8
North Italy	9.8
South Italy	5.8

In the first part of this paper we have shown the percentage of cancer of the stomach and cancer of the oesophagus in all deaths in various parts of Switzerland. In the south of Switzerland the population is almost entirely Italian in the western cantons the French predominate and in the northeast part the Germans. Again we see that the Italians are less prone to cancer of the oesophagus and stomach.

On the whole cancer of the oesophagus and stomach seems to be much less prevalent among the natives of the tropical and sub-tropical countries probably for the reason that a hot climate is inducive to frugality in diet in general and therefore the habit of taking large quantities of hot fluids is less likely to form.

CONCLUSIONS

1. Cancer of the oesophagus and stomach is peculiarly prevalent among the inhabitants of the temperate climate zone.

2. The relative frequency with which necrotic strictures from swallowed corrosive fluids occur in the various parts of the oesophagus increases from above downward in other words, the widest parts of the oesophagus are the most frequent sites of such strictures—and for physiological reasons.

3. The distribution of cancer in the oesoph-

agus corresponds to that of the cicatricial strictures from swallowed corrosive fluids and in all probability for the same physiological reasons

4 Any part of the oesophagus and stomach may be the starting point of cancer with the exception of the pyloric sphincter which rarely seems to be the primary focus. The organ immediately beyond namely the duodenum is practically immune from cancer. The reason for the two latter phenomena is probably that the ingesta do not reach the pyloric sphincter until they are properly modified

5 In view of the foregoing conclusions it seems logical to look to the ingesta of civilized man for the source of chronic irritation which lead to malignant changes of the oesophagus.

6 The supposition that swallowed fluid after emanating from the cardia are directed along the gastric gullet to the prepyloric region is strongly supported by the fact that the cicatrices from smaller quantities of swallowed corrosive fluid are usually found along this path

Seventy nine per cent of cancer of the stomach are also found along this path—the cardia the gastric gullet and the prepyloric region

8 As cancer of the stomach follows the highway of the fluid it seems logical to assume that ingested fluids in particular may be responsible

9 Alcohol and other irritating fluids probably play a part but in the opinion of the writer hot fluid so universally taken throughout the temperate climate zone in the form of coffee tea soups etc and giving rise to chronic irritation is the main predisposing cause of cancer of the oesophagus and stomach

10 Cancer of the oesophagus occurs less often in women than in men because women drink more slowly and take smaller swallows which pass quickly through thus saving the oesophagus while the less resistant mucosa of the stomach where the fluids come to a stop is more equally exposed in both sexes

11 The fact therefore that the ratio of cancer of the oesophagus in men and women is 3 to 1 while cancer of the stomach occurs

with almost equal frequency in both sexes points strongly to hot fluids as the important predisposing cause

12 This is further substantiated by the results of a comparison between the cancer statistics and the habit of the people in the north and south of Europe by the relative freedom from cancer of the oesophagus and stomach enjoyed by the aborigines of hot climates and the extremely rare occurrence of cancer of the oesophagus in infants

RUPTURE OF BLADDER ASSOCIATED WITH FRACTURE OF PELVIS

WITH BIBLIOGRAPHY AND REPORT OF ONE CASE

BY E. P. QUAIN, M.D., F.A.C.S., BISMARCK, NORTH DAKOTA

PROGNOSIS in intraperitoneal rupture of the bladder is as a rule either very good or very bad. The injury is either promptly diagnosed and successfully repaired or it is unrecognized or unsuccessfully treated and death from peritonitis follows in a few days.

In extraperitoneal rupture death does not usually come within the first three or four days even if the treatment has been inefficient or absent. The urine infiltrates through the soft parts in front below and behind the bladder and eventually comes to the surface through the inguinal canal through the femoral opening in the perineum or the prevesical space and is then often afforded an exit by incisions through the skin. All the urine may not extravasate into the tissues. The extravascular tension may become so great that a large amount of urine accumulates in the bladder and is thence evacuated normally or withdrawn by catheter. Prognosis so far as immediate mortality is concerned is not therefore as bad as in intraperitoneal rupture. In point of morbidity however the writer believes with Fuller¹ that most patients with extraperitoneal rupture of the bladder are left seriously invalidated for life.

The invalidism is due to several causes. The extravasation of urine is followed by infection suppuration and necrosis. The sloughing may become very extensive and in case of recovery lead to cicatrization contraction and loss of normal function of ureter bladder urethra or sexual mechanism. Another cause of more or less permanent disability is fracture of the pelvis which very often is associated with ruptured bladder. The bladder is perforated by a splinter of the fractured bone in most instances. But the two accidents fracture and bladder laceration may occur separately though from the same accident the overfilled bladder ruptur-

ing from a continuation of the force which caused pelvic fracture with wide separation of the fragment. This undoubtedly took place in my own case reported below. Even if the fracture is not in continuity with the bladder wound the extravasated urine is likely sooner or later to invade the site of fracture and to complicate it by adding infection.

Bladder laceration and pelvic fracture present for treatment two separate and very grave lesions. A study of the authorities shows a unanimity of opinion that the bladder should be drained promptly suprapubically by preference though a retention catheter in the urethra has served the same purpose in many cases. Suture of the tear is often unnecessary when the bladder is efficiently drained. On the other hand in the management of the bone fragments no such definite plan has been employed but most cases have been disposed of simply by applying a tight bandage about the hips. Direct treatment of the fragments by suture wiring etc. has been practiced on a few occasions but found unsatisfactory in the presence of urine and infection at the seat of fracture. Indirect fixation of the pelvic bone fragments by means of percutaneous screw and external clamps at points distant from the fracture and extravasated urine has not previously been described. The usefulness of this method is shown by the following report.

A boy 16 years old was brought to the hospital thirteen hours after the accident. While leading a colt with a long rope the colt broke away and ran dragging the boy about four hundred feet by the rope which had become entangled about the boy's right leg. The boy got up and stumbled along for several hundred feet before he fell unconscious. He had no recollection later of having walked or of anything that had happened after the horse made the first few jumps. It was noticed that urine and blood escaped profusely through a perineal wound. Since regaining consciousness some two or three hours later he had had a constant severe pain chiefly in the sacral region.

On examination he was found to suffer from shock and loss of blood seemed conscious, and complained of extreme pain in the pelvis. The left scapula was fractured transversely. There was wide separation of the symphysis pubis and the entire left os innominatum could be moved about freely upon the sacrum. A lacerated wound in the perineum two inches long and located to the left of raphe had torn through the anal mucous membrane, sphincter ani and muscle wall of rectum upward for an inch. This wound extended around the urethra to the left and opened into a large cavity bounded in front by the separated pubic bone fragments and the rectal muscles above and behind by peritoneum stripped loose from the abdominal wall and limited below by the collapsed bladder which was torn loose from its pubic attachment. A two and one-half inch curved laceration encircled two-thirds of the neck of the bladder on the left side. X-ray plates showed that outside of the separation of the symphysis and marked separation of the left sacro-iliac joint there was no further fracture of the pelvic bones.

A few hours later after recovery from shock, operation was performed. The bladder wound was sutured with one row of eight interrupted chromic catgut sutures. Three similar sutures closed the sphincter and rectal wall. The perineal wound was partly closed a rubber drain placed in front of the bladder and a permanent catheter through the urethra. The separation of the pubic bones was so marked and the fragments were so extremely movable that it was evident that some fixation of the bony pelvis was necessary. An attempt at tight strapping about the hips had been found inefficient to hold the symphysis together and to control the excruciating pain in the sacro-iliac region. The expedient of external fixation of the fragments by means of Freeman's screws and clamp was then adopted. A small incision was made on each side of the symphysis through healthy tissues, down to the bodies of the pubic bones, and the screws inserted. The bones were approximated and the external clamp applied.

The pain in the back subsided rapidly after the bone fixation. The perineal wound however was infected from the beginning, the bowels having moved involuntarily both before and after the operation. All urine came through the urethral catheter during the first week. It was bloody-purulent and filled with motile bacteria. The general condition improved steadily and the wound healed with surprising rapidity. Daily acetic acid irrigations of the bladder were employed to prevent incrustations. On the eighth day a urinary leakage through the perineum appeared. This increased in amount until the fifteenth day when the catheter was permanently withdrawn from the urethra. Natural urination began at once and increased in volume so that at the end of the first month there was but a slight perineal leakage. A small fistula through which a little urine discharged every five

or six days, persisted for several months, but finally healed entirely.

The Freeman screws in the pubic bones loosened and were removed on the twelfth day and a sacro-iliac belt applied. Bony union was not expected in the presence of infection but the bones were held in fair approximation while a firm and serviceable fibrous union was established.

The patient left the hospital after nine weeks treatment. His urine was still purulent and a slight perineal fistula was present but he was able to walk and had partial control which enabled him to hold his urine for an hour or two at a time.

A recent letter, two years after the accident states that he occasionally has partial urinary incontinence while in the erect position but he has perfect continence during the entire night, is free from pain has pulsance, and is in good general health. He belongs to the class which has recovered, although it is not fully cured. The tendency to incontinence is undoubtedly due to retraction in the cicatrix at the bladder neck which interferes with the sphincter function when he is standing.

The writer has conducted what is believed to be a fairly complete search of the literature and collected 126 cases of rupture of the bladder associated with fracture of the pelvis, a synopsis of which is submitted herewith. In the majority of these cases it was found that a spicule of bone had perforated the bladder. Most lacerations thus caused were extraperitoneal and several were multiple. With the exception of the instances where a foreign body had entered the pelvis from without (gunshot etc.) only four cases in which a lacerated bladder communicated with the outside have previously been described.

The treatment of the fracture itself is mentioned in only a few of the reported cases. With two or three exceptions it has evidently been limited to the application of a bandage around the pelvis after possibly some readjustment of the fragments. The treatment has often been seriously complicated by infection and necrosis of the bone.

Of the 127 cases now reported 34 recovered, making a total mortality of 74 per cent. But of these were 83 cases reported before 1890 with a mortality of 72 or 86.7 per cent. Of 44 cases since 1890 i.e. during the period of aseptic surgery 23 lived—a mortality of less than 48 per cent. As a further proof of the increasing efficiency of

OLIGURIC RUPTURE OF THE BLADDER

scientific surgical treatment in this class of injuries we may note that out of 1 cases reported since 190 only 8 died reducing the mortality to 38 per cent. No doubt this figure may be discounted to some extent by an increasing tendency to report only successful cases. The earlier reports were largely from autopsy protocol.

The total mortality in all varieties of bladder ruptures which have been treated surgically since 1900 is less than 5 per cent. This shows in figures the extreme gravity of the lesions under discussion and indicates that fracture of the pelvis is the most serious complication of a ruptured bladder.

There is no reliable method of learning the facts about postoperative invalidism in these cases, but it is to be hoped that with the general advance in surgical technique the ratio of improvement in result in the resected patient may become equal to the improvement in mortality.

crushed under a heel and sustained a rupture in the anterior wall of the bladder separating the sacro-macrosymphysis and causing a fracture of the sacrum. Edema of the perineal skin and the labia minora were made this day. The patient was at home 10 months. Patient sent to the hospital 1 year later.

The results of the analysis of variance are presented in Table 1. The analysis of variance for the first experiment revealed that the interaction between the treatment and the sex was not significant. The analysis of variance for the second experiment revealed that the interaction between the treatment and the sex was not significant. The analysis of variance for the third experiment revealed that the interaction between the treatment and the sex was not significant.

Male, aged 32 was run over. Bloody urine by catheterization. He died the fourth day. Autopsy: rupture in right side leading into small cavity in cellular tissue infiltration laceration of symphysis pubis.

CASE 30. Hewett, Lancet, Lond. 850, 1, 573. Patient, man of 3 years, was crushed by falling timber. Upon catheterization no urine as obtained. Urination of abdomen etc. free urine escaped after incision of urethra and swollen parts. Patient died the fourth day. Autopsy: fracture of pelvis rupture of bladder behind symphysis communicating with cavity containing pus, etc.

CASE 31. Hewett, Lancet, Lond. 85 573. Patient, male aged 34 fell from a height and died in house. A tony rupture of bladder behind pubes separation of symphysis pubis and fracture of pelvis.

CASE 32. Warren, Am. J. M. Sc. 85, xiii. A man of 30 was crushed by fall of earth and died on the way to the hospital. Autopsy: peritoneal cavity filled with blood rupture of bladder posterior to symphysis fracture near symphysis through ilium etc.

CASE 33. Currie, Med. Press & Circ. 853 405. A male aged 35 was caught under a cart and sustained pelvic fracture. Operation after 24 hrs. Incision 1/2 inches between tuber ischi and anus, evacuation of peritoneal urine retention catheter. Patient recovered in 4 months.

CASE 34. Warren (854) in Lesur. Thiers de doct. Par. 1833. A man of 30 was crushed and died in an hour. Autopsy: rupture of bladder behind symphysis pubis separation of symphysis fracture of pelvis.

CASE 35. Stanley, Brit. M. J. 857. A boy of 8 was injured by gas falling on him and died on the sixth day. A tony fracture of right pubis, separation of sacro iliac synchondrosis four ruptures in bladder etc.

CASE 36. Dubreuilh, Bull. Soc. Anat. d. Par. V. p. 7. Patient, male sustained accident producing luxation of all pelvic articulations pelvic fracture and other extensive injuries including rupture of bladder. Treatment, etc. not mentioned. Patient died.

CASE 37. Croly, Dublin Med. Press & Circ. 850. A man of 66 was run over. He was catheterized (clear urine) but had no inclination to urinate. Patient died the second day. Autopsy: fracture of right pubis rupture of bladder anteriorly urinary infiltration.

CASE 38. I. Wre. Bull. Soc. Anat. d. Par. 863, xxxviii. Patient, male was injured in accident and died in 4 days. A tony: meniscus pelvis fractures transverse rupture of bladder posterior wall.

CASE 39. Shoemaker, Nederl. Tijdschr. Geneesk. 86. Male aged 35 as injured in fall. Retention of urine blood by catheterization. He died after 4 days. Autopsy: separation of symphysis and fracture of pubis.

CASE 40. Harrison, Dublin M. J. 860. A boy of 12 years six months, as run over. He had voluntary urination developed erysipelas the fourth day and died the tenth day. A tony: rupture of anterior wall of bladder separation of symphysis and fracture of pubis.

CASE 41. Truettford, Union Med. Par. 864 xiii. A man of 50 as crushed by fall of bricks he had tumor in the right thigh almost to knee, non-fluctuant. Catheter drew blood and urine, retention catheter. Tumor fluctuated the thirteenth day and incision was made over it. Evacuation of blood urine, pus, etc. Fracture very possible. Wound base of bladder and one on the right side healed in 30 days. Recovery.

CASE 42. Rose, Charité Ann. Berl. 865. A male, aged 55 fell from a tree. He died from the urethra and catheter proved useless, after 4 days urine and blood etc.

passed spontaneously and in 1/2 months a urinary fistula developed. Urethromy performed after 4 months. Patient died. A tony: united fracture of pubis catheter found in cavity between bladder and rectum.

CASE 43. Fleming, Dublin Q. J. M. Sc. 866, xiii. A man of 60 was injured by wall falling on him. Bleeding through urethra he died in 48 hours. A tony: rupture of bladder anteriorly separation of symphysis and fracture of sacrum.

CASE 44. S. Mes, Dublin Med. Press & Circ. 866 1, 574. A man, aged 45 was injured in a fall. When seen 8 days later he had retention of urine upon catheterization blood, urine and pus were obtained tumor over hypogastrium. He died the twelfth day. A tony: two ruptures in anterior wall of bladder separation of symphysis peritonitis.

CASE 45. Shaw, Lancet, Lond. 1867 1, 74. A man of 50 fell while drunk. Blood and urine by catheterization there was tumor in hypogastrium and iliac region later voluntary bloody urine. Patient died the fifth day. A tony: both pubic bones were fractured the left pubis perforated the bladder & perineal infiltration.

CASE 46. Williams, Am. J. M. Sc. 867, lili 446. A woman aged 51 was run over. Bloody urine obtained by catheterization. She died in 48 hours. Autopsy: rupture of bladder by piece of fractured ilium.

CASE 47. B. Simpson, Am. J. M. Sc. 1868, iv. Male aged 55 injured in fall. He could not urinate there was rent in the neck of bladder and compression of the ureters of the uterus urine escaping through wound. Abscess developed. He died in bed for more than 10 weeks suffering from extensive suppuration. Patient recovered two years voluntarily suffering.

CASE 48. Grant, Austral. M. J. 868, xlii. Male aged 51 fell from a horse. Catheterization also red blood in bladder. He died in 36 days. A tony: blood in peritoneal cavity separation of symphysis with rupture of bladder behind.

CASE 49. Seely, Am. J. M. Sc. 868 1, 4. A man aged 35 crushed by heavy man. Blood by catheterization. He died the fourth day. Autopsy: separation of symphysis rupture in anterior part of fundus infiltration.

CASE 50. Logan, New Orleans J. Med., 870, xlii. A male aged 43, jumped from second story. Blood obtained by catheterization. He died. A tony: fracture of sacrum separation of symphysis pubis rupture of bladder beneath perineum.

CASE 51. Clark (87), in Bartels, Arch. f. Klin. Chir., 1878, xxi. A man, aged 30 as crushed. Peritoneal section made the third day blood and urine coming from wound he died the twenty-fifth day. A tony: rupture of bladder fracture of pubis and ilium.

CASE 52. Gross, Systems of Surgery, Philadelphia. 87. Patient young man, as injured in fall. He was unable to urinate and there was infiltration of urine into perineum etc. He died from peritonitis and gangrene 10 weeks after the injury. A tony: rupture of bladder fracture of ilium and pubis.

CASE 53. Smith, Dublin J. 87, lili 51. A female, aged 60, as run over had retention blood obtained by catheter tumor in iliac region. She died the nineteenth day. Autopsy: laceration of neck of bladder fracture of ilium and both pubes.

CASE 54. Dorech, Bartels, Dublin J. 873, lili. A man of 40 was crushed between cars. Anus, peritonitis he died in 48 hours. A tony: rupture of bladder separation of symphysis, deep depression of left pubic bone.

CASE 55. Dickenson and Holmes, St. George Hosp. Reports, Lond. 874, viii. A man aged 4 was injured

in a fall he fractured the ilium ruptured the bladder anuria following. Perineal section made patient died in 43 days. Autopsy rupture of bladder with fracture.

CASE 46. Jenden Deutsche Zeitschr. f. Chir., 1884. A male aged 35 was injured in a fall after which there was extensive suppuration in the bladder region. He was operated on the twentieth day through the right inguinal canal through which blood and urine were evacuated. Patient died in 6 months. Autopsy fracture of pubis and perforation of bladder.

CASE 47. Rudell Austral. M. J. 84. A male aged 36 injured by falling a horse fall on him died after 3 days. Autopsy separation of symphysis transverse rent in anterior wall of bladder.

CASE 48. Teissler Lyon med. 85. A male, aged 25 was crushed under a heavy mass. Blood and urine by catheterization. He died the third day. Autopsy six fractures of pubis corresponding to 3 ruptures of bladder bones perforating.

CASE 49. Barth Bull. Soc. anat. de Par. 1866. A man of 55 was run over. Blood and urine by catheterization. Patient died the second day. Autopsy extravasation of blood and urine subperitoneally, separation of symphysis pubis fracture of sacrum and pubis perforation of bladder.

CASE 5. Fleming Clinical Record of the Injuries and Diseases of the Genito-Urinary Organs. Dublin 187. Patient a man of 43 injured in a fall. He was taken to hospital after one week anuria tumor in hypogastrium. He died in 5 days. Autopsy cavity behind abdominal muscles filled with blood urine contracted bladder behind this fracture of sacrum, separation of symphysis pubis.

CASE 51. Fleming Clinical Record of the Injuries and Diseases of the Genito-Urinary Organs. Dublin 8. A boy of 7 was run over shock and collapse retention catheter. He died after 8 days. Autopsy fracture of both pubes with penetration of bladder.

CASE 5. Heath, Lancet Lond. 877. A man of 4 was injured by an engine bed falling on him shock scrotal swelling etc. bloody urine by catheterization. He died after 16 hours. Autopsy subperitoneal infiltration tear in anterior wall of bladder separation of symphysis pubis and sacro-iliac synchondrosis.

CASE 53. McDougall Edinb. M. J. 1877 Jan. Patient a man, was run over while drunk. Blood by catheterization symptoms of peritonitis tumor over pubis, fracture of ilium demonstrated treated by retained catheter followed by recovery.

CASE 54. Augur in Chaboureaux's Thesis de doct. Par. 1878. A man was run over and died in a few hours. Autopsy multiple fractures extraperitoneal rupture of bladder.

CASE 55. Bartels Arch. f. klin. Chir. 89. A man of 50 was injured by a horse falling on him. Examination showed fracture of pubes, bloody urine by catheter anuria extravasation relieved on tenth day by incisions. Slow recovery began using crutches after 6 months able to walk after 3 months all 6 years later but suffering from fistula etc.

CASE 56. Chaboureaux, Thesis de doct. Pa. 1878. A man of 24 was run over and died after 4 days. Autopsy multiple fractures rupture in anterior wall of bladder.

CASE 57. Chaboureaux Thesis de doct. Par. 1878. A boy of 4 was run over. Perineal incisions made for infiltration. He died in 6 days. Autopsy fracture of pelvis with extra-peritoneal rupture of bladder.

CASE 58. Chaboureaux, Thesis de doct. Par. 1878. A man was run over and died in 4 hours. Autopsy separation of symphysis pubis rupture of bladder posteriorly.

CASE 59. Demme in Bartels Thesis de doct. Par. 1878. A man of 18 was injured by tree falling on him. He was unable to urinate each morning groin catheter drew a few drops of bloody urine only in 15 on third day he died the sixth day. Autopsy fracture of pubis with a fragment perforating the bladder.

CASE 60. Curitt Hosp. Gaz. N. Y. 878. A male aged 31 was struck by a Retention of urine bloody urine by catheterization perineal incision and evacuation after 4 hours. He died in 3 days. Autopsy fracture of both pubes rupture of internal wall of bladder.

CASE 6. Cuenzberg Hosp. Gaz. N. Y. 875. A man of 45 was struck by a beam. He was unable to urinate and died in 60 hours. Autopsy rupture of bladder near symphysis fracture of ilium and pubis.

CASE 62. Louis in Bartholem. Fran. med. Par. 89. A man of 51 was injured in an accident and died after 7 days. Autopsy rupture of anterior wall of bladder fracture of pubis bone fragment penetrating bladder.

CASE 63. Velstein in Chaboureaux Fran. med. 878. A woman was run over and sustained a fracture of the pubis with a piece penetrating bladder and vagina fragment removed through glans. She recovered.

CASE 64. Knauth in Bartholem. Fran. med. 1878. A man of 4 was injured in a fall and died in 4 days. Autopsy quadruple fracture with piece of pubis penetrating bladder.

CASE 65. Barth Bull. Soc. anat. de Par. 1866. A man of 36 was run over and died in 3 days. Autopsy double fracture in pelvis and double rupture of bladder.

CASE 66. About from Chaboureaux. Man aged 3 was injured in a fall and died in 4 days from separation of symphysis pubis and extraperitoneal rupture of bladder.

CASE 6. Vollemmer from Chaboureaux. A male, aged 4 injured in an accident weight falling on his abdomen. Ruptured bladder fracture of pubis with separation of sacro-iliac synchondrosis. He died in 5 days.

CASE 68. Morris Lancet Lond. 883. A boy of 15 was run over. Blood by catheterization iliac swelling median incision after 10 hours showed blood in peritoneum no rupture found. Patient died after 24 hours. Autopsy fracture of both pubic bones rupture in anterior wall of bladder.

CASE 69. Rivington Lancet, Lond. 1882. A man of 4 was injured in a fall. Blood and urine by catheterization scrotal swelling. He died in 4 days. Autopsy fracture of ischium and pubis neck of bladder ruptured.

CASE. Stone Med. News, Phila. 1883. A male aged 2 crushed between cars sustained a laceration into peritoneal cavity through which urine escaped no urine by catheterization retention catheter applied. He died on thirty-fifth day. Autopsy separation of symphysis rupture through base and neck of bladder.

CASE 7. Alexander Liverpool Med.-Chir. J. 1884. A man of 41 was run over. Bloody urine by catheterization abdominal section made in 16 hours revealed rent in bladder by spicule of bone. He died the second day. Autopsy fracture of pubis fracture of sacrum laceration of bladder.

CASE 7. Cohn Bull. Soc. anat. de Par. 1866. A man of 56 was run over. Anuria bloody urine by catheterization. He died in 65 hours. Autopsy no infiltration of urine double fracture of sacrum bladder perforated behind symphysis by rupture of ligament.

CASE 73. Harrison Liverpool Med.-Chir. J. 1884. A man of 20 fell with a big stone on top of him. Blood and urine by catheterization median perineal incision.

made in 24 hours drainage established after exploration of bladder. Patient died the seventh day. Autopsy pelvis fractured in 6 places laceration of bladder in anterior wall and trigone.

CASE 74. Willard Maryland M J, 55; xll. A male, aged 3, was crushed under an engine. Anuria blood and urine by catheterization. Patient died in 3 days. Autopsy separation of symphysis, left pubis penetrating bladder fracture of ischium, etc.

CASE 75. Schrady Med. Rec., N Y 836 xxx, 44. A man was caught between wheels. Extra sation of urine operation in 24 hours, suprapubic cystotomy drainage established. He died the fifth day. Autopsy rupture of bladder urethra torn across multiple fractures of pubes and ischium, etc.

CASE 76. Hofmoll, Wien. med. Presse 886 xxvii, 7. Male, aged 27 fell from height and sustained double rupture (intra and extraperitoneal) of the bladder with disjunction of symphysis pubis and open fracture of right pubis. Laparotomy was performed 4 hours later, blood and urine found in perivesical cavity. Intrapertoneal rupture of fundus of bladder sutured, extraperitoneal rupture of bladder left open and drained and retention catheter left. Patient recovered slowly.

CASE 77. Briddon, N Y M J 887, xl M le, aged 33 was injured by stone falling on him. Blood urine by catheterization. Laparotomy in four and one half hours, permanent catheter inserted and drainage established. There was double fracture of pubes, rupture of anterior wall of bladder catheter removed the seventh day. Patient recovered, female present 7 months later.

CASE 78. Briddon, N Y M J 887, xlv Male, aged 4 was struck by locomotive. Blood urine per catheter perineal incision 6 hours later tube left in bladder suprapubic incision and drainage. There was a fracture of pubis with rupture of anterior wall of bladder. Patient died the sixth day. No topos.

CASE 79. Mason, Lancet, Lond 557, i, 7. A man, aged 36 was crushed by wagon. Bloody urine by catheterization. Incision over pubes, retention catheter applied. Patient died the seventeenth day. Autopsy fracture of pubes, right pubis pushed into bladder.

CASE 80. Robson Brit M J L Male, aged 65 was operated on for ruptured bladder but died 16 hours later. Autopsy showed perforation of anterior wall of bladder by bone fragment from comminuted fracture of pubes.

CASE 81. De Arx in Cor BL f Schweiz. Aerzt 833. A male sustained a fracture of pubis in an accident. Laparotomy performed and bladder found ruptured and was drained by retention catheter. Patient died after 24 hours. Autopsy showed bladder to be torn by fractured pubes, extraperitoneal hemorrhage.

CASE 82. Bond Lancet, Lond 830, Aug 4. A man, aged 34, was crushed by heavy mass. Laparotomy and exploration of bladder the third day. Patient died. Autopsy bladder lacerated 1 inch, fracture of ischium.

CASE 83. Dehollere Lyon med 889 March. A man was injured in fall. Fracture of both pubes with fragment penetrating bladder near the base extravasation also into peritoneal cavity. Operation in 24 hours through perineum retention catheter. Recovery.

CASE 84. Rowe Deutsche Zeitschr f Chir 80 xxx, 347. A male, aged 3 injured in fall. Suprapubic operation after 48 hours, rupture in anterior wall of bladder fracture of sacrum and pubes. Suprapubic drainage no sutures, continuous bath. Recovery in 6 months.

CASE 85. Imbrico Gior med d r oeristo etc., Rome 803 xl, 44. A man accidentally injured suffered an extraperitoneal laceration of the bladder together with fracture of pubes, and died in 7 days.

CASE 86. Arnheim, Deutsche med Wchnsch 1893 xix, 48. Female aged 41 operated after a pelvic injury found to have double extraperitoneal rupture of the bladder caused by penetrating pelvic bone fragments. Suprapubic operation with suture of bladder wound. She died the twentieth day.

CASE 87. Arnheim Pest med chir Presse Budapest, 803 xvi, 267. A man hurt in fall had laceration of the bladder and separation of symphysis pubis. Operation in the eleventh day wiring of symphysis, permanent catheter. Result extrusion of sequestra but recovery in 4 months.

CASE 88. Parker Societ of Clinics of London, 803 Jan 7. A boy 9 years old struck by car sustained fracture of the femur separation of symphysis pubis and rupture of the bladder. Operation suprapubic incision and drainage. Recovery.

CASE 89. Beckman Thoms de doct, Halle, 806. A man of 4 after pelvic injury was found to have an extraperitoneal rupture of the bladder with fracture of pelvis. Operation section with suture of bladder wound, retention catheter. Recovery in 3 months.

CASE 90. Cushing in Mitchell Ann Surg Phila 806 viii, 5. A man of 31 was crushed by heavy weight. He was operated on after 30 hours. Suprapubic cystotomy retention catheter. He died the fourth day. Autopsy result pie fractures perforation in anterior wall of bladder.

CASE 91. Van Slooten, Nederl med geneesk Arch 806 v, 33. Case of man run over. Operation showed extraperitoneal rupture of bladder with separation of symphysis and fracture of pubes. Suprapubic incision, retention catheter. Patient died in 4 hours.

CASE 92. Wacziarg, Zeitschr Feler d 8 Jaehr f d Aerzte Vortr zu Hamburg 806. Patient, man of 30 injured by heavy mass falling on him and operated 4 hours later. He was again operated the 7th day. Fracture of pubes with extraperitoneal rupture of bladder. Patient discharged as cured in 3 months.

CASE 93. Sub user (Muenchen) Muenchen 804. A man of 50 was crushed by locomotive and sustained fracture of pubes blood obtained by catheterization hypogastric incision made and drainage established retention catheter. He died the second day. Autopsy fracture of both pubes, bone fragment penetrating bladder diaphragm of left sacro iliac, symphysis.

CASE 94. Masciarelli Bull Soc anat de Par 807 p 860. A man was crushed by heavy block of stone. Symptoms of peritonitis laparotomy perforation of bowel, rupture of anterior wall of bladder fracture of ilium and pubes. He died 4 hours after operation.

CASE 95. Mitchell Ann Surg Phila 808 xxvii, 5. A man aged 5 fell from wagon and was crushed under wheel. Operated on 7 hours later fracture of left pubis and extraperitoneal rupture of bladder bladder wound sutured, patient kept in continuous bath for 40 days. Fully recovered in 9 months.

CASE 96. McLaren (806 case), J Am M Ass 808, xxx, 308. A man crushed by fall of bricks sustained fracture of the left pubis, bloody urine by catheterization, tumefaction of scrotum, etc. Operation, inguinal and perineal incision. Later secondary lumbar abscess treated. Recovery.

CASE 97. Biss, Bull Soc anat de Par 800 p 950. A man fell from height on the right side against heavy object, sustained multiple fractures of the pelvis, and died after 8 hours. Autopsy rupture of anterosuperior wall of bladder caused by bone fragment, fracture of pubis, sacrum, etc.

CASE 98. Lohrer, Bull Soc anat-clin de Lille, 800 p 733 cited by Jnoon. Male aged 43, was injured in

a fall Operation suprapubic cystotomy no bladder rupture was found. He died in 4 days. Autopsy three ruptures in bladder fracture of the two pubic bones etc.

CASE 90. Roedmann Thes de doct Leipzig 1800
A boy of 15 was injured by being hit falling on his abdomen abdominal tumour in 4 hours fracture of right pubis at the junction of blood urine. Operation bladder ruptured near neck sutured retained catheter. Rapid recovery.

CASE 100. Roedmann Thes de doct Leipzig 1800
A boy of 15 fell from a height on to a hard substance and sustained multiple fracture including fracture of the pelvis. He died 48 hours after the accident. Autopsy extensive renal rupture. Anterior wall of bladder.

CASE 0. Koedmann Thes de doct Leipzig 1800
Male aged 40 while drunk rubbed betwixt all and a dog. A fracture of the pelvis was found and no urine was obtained per catheter. He died the same evening. Autopsy separation of the pubic bones. Blood in peritoneal cavity rupture of anterior wall of bladder.

CASE 0. Mailland L. med 1801
Male aged 68 injured in a fall perineal extent but died on the 11th day. Autopsy showed a rupture of the bladder perineal at base of prostate.

CASE 0. Johnson Ann d. mal d. genit urin 1800
A man aged 40 was rubbed by a woman and sustained a pelvic fracture. Blood and urine in catheter. No extent in the rectum. He died the same operation. Rupture of bladder found at perineal extent all which was due to bone fragments. He died 5 days after the accident. Autopsy fracture of both pubes in addition to bladder perineal.

CASE 0. Baz Bull N. d. hi Par 1800 Mar
A man was injured in a fall from a horse and sustained a double fracture of the pelvis and rupture of the bladder. Hæmaturia and perineal incision made. Patient died.

CASE 05. Astuc Thes de doct Montpellier 1801
Male aged 40 sustained a fracture of the pubis and extensive renal rupture. Bladder found in gunshot wound. No urine obtained. Catheterization suprapubic. Incision made next day and three parts of the bone removed from the bladder. No urine drainage and retention with fever. In 4 months patient recovered without fistula.

CASE 100. Eastman N. M. J. 1803 LXVII 05
A man of 30 years was injured by a weight falling upon him. Pubic arch was driven in. No right and blood and urine per catheter. Suprapubic incision made. Spicule of bone of ramus of pubis penetrating anterior wall of bladder. Fracture of distal bladder drained and tamponed. Recovery.

CASE 0. Eastman N. M. J. 1803 LXVII 05
Male injured in a railroad wreck. Bladder and rectum impaled by sharp instrument. Fracture of ilium fracture of femur rectal and bladder wounds sutured. Retention catheter. Natural urination after 3 days. Recovery.

CASE 100. Eastman N. M. J. 1803 LXVII 05
A man crushed under a heavy mass sustained a fracture of the pelvis with rupture of bladder. Pubic arch driven in, anterior wall of bladder and roof of prostatic urethra torn. Bladder not sutured but urethral and suprapubic drainage bone reduced. Recovery.

CASE 100. Morel Ann d. mal d. org. genit-urin 1806 XL
Male aged 40 received a crushing injury. Blood per catheter. Operation next day. Anterior wall of bladder ruptured by bone fragment from iliopectic fracture suprapubic drainage. Patient died after operation.

CASE 110. Marnoch Ann Surg Phila 1806 XLIII
A woman of 40 fell 10 feet striking side of pelvis.

Fracture of pelvis demonstrated by palpation. Operation after 4 hours. Extraperitoneal rupture of bladder. Much was uterine and retained in the uterus. It was discovered at the hospital in 4 months.

CASE 1. Lepe C. M. J. 1800 100 Male
A man was injured by a fall on his back. No fracture demonstrated. No urine in bladder. Urine in the urethra. Perineal incision made. No urine. Bladder fractured in the pubic bone. Perineal incision made. Bladder fractured in the anterior wall.

CASE 1. Bell C. M. J. 1800 100 Male
A man was injured by a fall on his back. No fracture demonstrated. No urine in bladder. Urine in the urethra. Perineal incision made. No urine. Bladder fractured in the pubic bone. Perineal incision made. Bladder fractured in the anterior wall.

CASE 1. Bell C. M. J. 1800 100 Male
A man was injured by a fall on his back. No fracture demonstrated. No urine in bladder. Urine in the urethra. Perineal incision made. No urine. Bladder fractured in the pubic bone. Perineal incision made. Bladder fractured in the anterior wall.

CASE 1. Bell C. M. J. 1800 100 Male
A man was injured by a fall on his back. No fracture demonstrated. No urine in bladder. Urine in the urethra. Perineal incision made. No urine. Bladder fractured in the pubic bone. Perineal incision made. Bladder fractured in the anterior wall.

CASE 1. Bell C. M. J. 1800 100 Male
A man was injured by a fall on his back. No fracture demonstrated. No urine in bladder. Urine in the urethra. Perineal incision made. No urine. Bladder fractured in the pubic bone. Perineal incision made. Bladder fractured in the anterior wall.

CASE 1. Bell C. M. J. 1800 100 Male
A man was injured by a fall on his back. No fracture demonstrated. No urine in bladder. Urine in the urethra. Perineal incision made. No urine. Bladder fractured in the pubic bone. Perineal incision made. Bladder fractured in the anterior wall.

CASE 1. Bell C. M. J. 1800 100 Male
A man was injured by a fall on his back. No fracture demonstrated. No urine in bladder. Urine in the urethra. Perineal incision made. No urine. Bladder fractured in the pubic bone. Perineal incision made. Bladder fractured in the anterior wall.

CASE 1. Bell C. M. J. 1800 100 Male
A man was injured by a fall on his back. No fracture demonstrated. No urine in bladder. Urine in the urethra. Perineal incision made. No urine. Bladder fractured in the pubic bone. Perineal incision made. Bladder fractured in the anterior wall.

CASE 1. Bell C. M. J. 1800 100 Male
A man was injured by a fall on his back. No fracture demonstrated. No urine in bladder. Urine in the urethra. Perineal incision made. No urine. Bladder fractured in the pubic bone. Perineal incision made. Bladder fractured in the anterior wall.

CASE 1. Bell C. M. J. 1800 100 Male
A man was injured by a fall on his back. No fracture demonstrated. No urine in bladder. Urine in the urethra. Perineal incision made. No urine. Bladder fractured in the pubic bone. Perineal incision made. Bladder fractured in the anterior wall.

CASE 1. Bell C. M. J. 1800 100 Male
A man was injured by a fall on his back. No fracture demonstrated. No urine in bladder. Urine in the urethra. Perineal incision made. No urine. Bladder fractured in the pubic bone. Perineal incision made. Bladder fractured in the anterior wall.

CASE 1. Bell C. M. J. 1800 100 Male
A man was injured by a fall on his back. No fracture demonstrated. No urine in bladder. Urine in the urethra. Perineal incision made. No urine. Bladder fractured in the pubic bone. Perineal incision made. Bladder fractured in the anterior wall.

CASE 1. Bell C. M. J. 1800 100 Male
A man was injured by a fall on his back. No fracture demonstrated. No urine in bladder. Urine in the urethra. Perineal incision made. No urine. Bladder fractured in the pubic bone. Perineal incision made. Bladder fractured in the anterior wall.

CASE 1. Bell C. M. J. 1800 100 Male
A man was injured by a fall on his back. No fracture demonstrated. No urine in bladder. Urine in the urethra. Perineal incision made. No urine. Bladder fractured in the pubic bone. Perineal incision made. Bladder fractured in the anterior wall.

CASE 3. Stocker Riv de med. chir. Prat., 9
XIV 249. Man operated on for gunshot wound of
pubis, fragment of bone found to have been detached and
penetrated bladder laterally; bladder wound not sutured
but drained. Patient died.

CASE 24. Naumann Nord. med. Ark., Stockholm
9 21 No. Boy of 7 crushed by railway car
operation showed fracture of pelvis and tear in bladder
drainage of bladder and peritoneal cavity. Patient
recovered, fistula healed after 3½ months.

CASE 5. Fuller J Am. M Ass 9 4 1211 14

Male aged 3 pelvis crushed between cars. Perineal
infiltration and incision. After months X-ray showed
pelvic fracture. Operation demonstrated bladder rupture
extraperitoneal. Patient recovered slowly.

CASE 26 Blackburn and Cook Lancet, Lond. 9 5
11, 3. Man of 45 years on suddenly jumping on
horse felt severe pain and fell to the ground, bloody urine
per catheter; operated 6 hours later ramus of left pubic
bone fractured bladder torn in prostatic region, bladder
packed and drained. Recovery fistula healed in 3
months.

PELVIC VARICOCELE

B. J. ALVARADO WALL, M.D. S. TIAGO, CHILE

Late Assistant Surgeon, Women's Hospital

AS the Chilean literature on the subject
of pelvic varicocele is scarce I thought
it might be of some interest to report,
with a few comments the clinical his-
tories of the cases I have observed.

There are two varieties of ovarian var-
icocele primary and secondary. The former
is not associated with other genital diseases
while the latter is the result of a growth or of
a pathological process in the pelvic organs
the ovary, uterus, or broad ligament.

A condition of paramount importance in
all varicose diseases, such as hemorrhoids,
varices, etc. is chronic inflammation of the
vein-wall the starting point of stasis there-
fore a microscopic examination is necessary
before varicocele can be definitely diagnosed
as it sometimes happens that instead of var-
icocele we have simply a venous dilatation.
It is well known that during pregnancy the
tubo-ovarian veins reach an enormous size
a fact which I had the opportunity of pro-
ving to my satisfaction in a patient upon whom
I operated in September 1914 for a carcinoma
of the uterus. The operation was performed
during puerperal involution and we were
considerably handicapped in the Wertheim
panhysterectomy because of the enormous
size of the vessels of the uterus and broad
ligament.

The same anatomical grounds in the male
explain the greater frequency of varicocele
on the left side the position of the spermatic
vessels behind the ilio-pelvic colon and the

anastomosis to the renal vein should be con-
sidered especially the first factor when aggra-
vated by chronic intestinal stasis so common
among such patients. These mechanical
elements are not however pathogenic we
have to take into consideration the condition
of chronic inflammation of the fibrous tissue
which English authors call fibrosis or fibrositis
and which is usually produced by a slight in-
fection (Adami).

It is not unusual for these women to pre-
sent a persistent edema of the ovary and
sometimes of the uterus such as the elephan-
tiasis of a varicose leg or the enlargement of
a testicle below a varicocele. After a variable
length of time this engorgement may end in
sclerosis and finally in atrophy.

A number of gynecologists call attention
to the relation between varicocele and fibro-
cystic ovaritis. It is interesting to note the
peculiar softness of the ovary and uterus
when we are fortunate enough to treat the
disease in a very early state before the fibrot-
ic processes have taken place and gained some
ground. The uterus is very soft, like an old
cloth, and its walls are compressible. Such
characteristics are not found in other con-
ditions which are accompanied by uterine
swelling with perhaps the single exception of
a uterus shortly after a miscarriage.

The symptoms are very unusual. The
patients, often multipara complain of pain
in the lumbar region and in the lowest parts
of the abdomen. The pains are aggravated

when the patient stands and during or near the menstrual period and they subside when the patient lies down or when the flow has started. As the physical signs are very poor and often quite negative these poor patients are relegated to the large group of so-called neurotic. The menses are abundant and irregular as to duration and date of beginning. Another symptom often mentioned in the clinical histories is pelvic varicocele and the watery leucorrhœa which is very difficult and tedious to treat and like the other symptoms is greatly aggravated during menstrual periods.

The physical examination is very often negative but in favorable cases we feel a hard lump situated below the ovary which is almost always swollen and flaccid at the bottom of the pouch of Douglas. When standing, the palpation will be more positive and when suspected we must have recourse to examination in this position.

The co-existence of varicose veins in the lower leg and labia will be of assistance in the differential diagnosis.

The diagnosis after all we have said may be considered difficult and usually made by exclusion as is the case in all diseases which are accompanied by a few physical signs.

If a patient complains of pains which are made more severe by standing or walking and which are ameliorated when lying down if these pains increase when the menstrual flow approaches and when the menses are very profuse then we have sufficient reason to suspect a varicocele more especially when palpation reveals a soft mass quite independent of the ovary and tube. If the perineum is flail not resistant and at the same time varices and a bluish color are to be seen on the collum uteri and vagina the diagnosis is fairly safe.

Chronic appendicitis is the commonest error made in diagnosing these cases. Some of these patients are subjected to appendectomy with of course negative results. Chronic metritis is the next most common error. This is very easy to explain if we remember that leucorrhœa and an increase in the size of the uterus are two of the most frequent symptoms of chronic metritis. Edema due

to venous stasis and the transudation of lymph is the cause of these conditions. The leucorrhœa is very peculiar in these cases and it was asked the patient more closely regarding it they always state that the fluid is watery like urine quite different from the yellow discharge in cases of metritis.

Some surgeons are of the opinion that fibrocystic ovaritis is often the result of pelvic varicocele. Other deny any relationship between these two diseases. Without entering into a discussion on this point I think the practical conclusion to be drawn therefrom is that now we have made the first diagnosis we are in a way authorized to deny the existence of the latter but on the contrary our duty in such a case is to investigate it.

With these incomplete comments and before going into particular as to treatment let us briefly summarize the complication or an unusual symptom.

There are in the medical literature some cases of retro uterine hæmatocèle and ovarian hæmorrhage which possibly may be attributed to rupture of a varicose vein. The bursting and bleeding may take place between the layer of the broad ligament thus giving rise to a hæmatoma the result of which is ultimately and usually a fibrous new growth a kind of fibroma.

In October 1914 I operated on a woman suffering from a uterine cancer and as I found in the vicinity of the uterus a lump the size of a hazelnut I feared it might be of the same nature and the operation useless. The tumor was situated below the right ovary and its surface gave the appearance of worm. The pathologist's report as fibroma. Unfortunately there were no further details.

As during pregnancy the varicose veins undergo a greater development it is not unlikely that profuse hæmorrhages may supervene and the treatment of this condition is sometimes very difficult. At the annual meeting of the American Medical Association held at Atlantic City in 1914 Zinke of Cincinnati gave the history of a woman 35 years old 18 weeks pregnant, who consulted him because of profuse hæmorrhage. He curetted her. The bleeding however continued during five

months, at the end of which time and knowing that she was again pregnant, he resorted to laparotomy. He found a soft mass which he believed to be para ovarian and which he removed. The patient recovered her pregnancy following uninterrupted its normal course.

The treatment should only be surgical if we aim to obtain a permanent cure. Medical ly we can relieve the condition of such patients if we advise the recumbent position and the correction of pelvic organs by means of a vaginal plug or a reconstructive perineal operation.

CASE R. G. age 38 III para two miscarriages, the last one a year before. Since then m. menstruations were very profuse and painful. She complains of pains in both loins and deeply in the hypogastrium. She feels tiresome sensation. At the beginning of June the pains became more marked and she vomited several times. She had an abundant serous leucorrhoea which she could differentiate from that of some of her relatives who suffered from chronic metritis. The portio vaginalis was enlarged, the corpus voluminous and soft. Behind and to the left in the deepest part of Douglas pouch, a round, even and soft mass is easily palpable and tender to pressure. It was believed by myself and other examining physicians to be sclerocystic ovary.

Median laparotomy June 26 1906. The left ovary was soft, enormous, and easily movable. The utero ovarian vessels were greatly distended. The left ovary and accompanying tube were removed and great portion of tubo-ovarian veins by means of an incision of broad ligament parallel to the round ligament were resected.

Once the varicocele was recognized we immediately inspected the opposite side and as we found it the seat of a beginning stasis we decided to pass two or three ligatures through its most conspicuous veins.

The uterus was enlarged, reddish blue in color and so soft that it could be molded between the fingers, condition not previously observed by us.

The removed ovary was cut along its median line, giving a splendid view of the engorged veins. Microscopical examination showed a varicocele and oedema of the ovary. The removal of this organ was, as is demonstrated, not justified.

CASE E. D., age 34 multipara. As a result of violent train five years ago she felt an intense pain on both sides of the lumbar region. The pain, though less severe has persisted since that time. The periods are irregular and painful. She complains of pain on the left side of the hypogastrium. The pain is more marked when menstrual flow approaches.

The right kidney is slightly mobile the uterus is small, a little retroverted and movable the left appendage is enlarged and tender to pressure. A diagnosis of retroversion of the uterus and left adhesion was made. Operation August 26. The left ovary and tube were absolutely normal. The tubo-ovarian venous vessels on the left side were more dilated than usual. The right ovary was microscytic. The veins were very large giving to the broad ligament rather striking bluish color. The most prominent vessels were ligated the appendix removed, and both round ligaments were shortened (Doléris Richelot).

It is interesting to note the co existence of sclerocystic ovaritis and varicocele. I think it is very likely that the former is the end result of a prolonged stasis. I do not claim to prove that such is the only cause of this enigmatic ovarian disease my object is to explain the relationship if any between the diseases.

The surgeon may find upon opening the abdomen that no veins appear and he may thus fear a mistake in diagnosis has been made but the explanation is very easy as the Trendelenburg position favors venous circulation the pelvic veins, following the general rule empty with incredible rapidity and everything appears normal. In the patient whose history I have just given and in the next one I could conclusively demonstrate this phenomenon. This is, I think the cause of mistake in a patient where the palpating hand very distinctly discovered besides the ovary and tube many soft and elongated masses which disappeared after prolonged pressure. I was justified in making a tentative diagnosis of pelvic varicocele and fibrocystic ovary. The operation did not confirm the pre-operative diagnosis.

CASE J. M. A. C. age 38 V para menses of four days duration until that time since then they are regular and last week. The portio vaginalis is large and hard the corpus is enlarged. The uterine probe induces bleeding. The right ovary is easily palpated, is the size of a peanut, and is soft, fluctuating and not tender to pressure.

Diagnosis cyst of right ovary chronic metritis. The laparotomy was performed under spinal analgesia (Jonesco) and the diagnosis verified. A varicocele of the same side was also discovered. The veins were enormously dilated and they completely collapsed as soon as the supine position was assumed.

We opened the layers of the broad ligament and

resected a few centimeters of the most prominent veins. The ovary was the seat of a serous cyst and covering the surface of the tube. There were numerous small cysts both ovary and tube were removed. The appendix was removed. The left broad ligament and appendage were normal.

From all we have said the conclusion to be drawn is that this disease is not so rare as is usually thought and as would be indicated in the papers written on the subject. It has

been regarded as an exceptional condition because we do not expect to find it and because even when diagnosed we sometimes fail to recognize it as happened to me.

PURPURA HÆMORRHAGICA FOLLOWING MENORRHŒA

B. FRANCIS ROE BENHAM M.D. S. R. C. L.

IN presenting a paper on the subject of purpura hæmorrhagica following menorrhœa it is not the purpose of the writer to discuss or percolate on the etiology of this condition. However the cause of the condition is and has been a matter of a great deal of theorizing and experimentation and I will therefore give a few of the theories advanced.

Briefly purpura hæmorrhagica may be defined as an abnormal condition of the blood or blood vessel and possibly both characterized by the appearance of hæmorrhages in different parts of the body. These hæmorrhages may be subcuticular submucous or subserous in fact they may appear in any part of the body. The subcuticular varieties appear under the skin and vary in size from a small pin point (petechiæ) to the large ecchymotic patch. The submucous is found as the name implies under the mucous membranes. Its size and appearance is not unlike the subcuticular. The subserous are found under the serous membranes.

The case which I shall report had all these different varieties of purpuric hæmorrhages.

There are many theories and opinions expressed as to the causation of this malady. Certain infectious diseases such as typhoid and malaria seem to produce a condition of the blood that not infrequently leads to attacks of purpura hæmorrhagica.

Letzenick believes purpura hæmorrhagica to be of infectious origin and has isolated a

bacillus not unlike the bacillus of anthrax. Auto-intoxication is said by others to be a causative factor in the production of this disease. It is thought that certain toxins absorbed from the intestinal tract so act upon the blood or blood vessel or both that coagulation is interfered with and as a result we have the hæmorrhagic diathesis with production of purpura.

Silbermann believes that in these cases blood pressure in the capillaries is greatly increased and as a result some of the small capillaries may rupture and thus throw blood into tissues. Again it is said to be produced by a process of diapedesis.

Kogerer and Silbermann who have spent much time in the study and experimentation of this condition summarize their work as follows. First the condition is the result of vascular disease. Second as a result of the vascular disease there is thrombosis formation. Third following the thrombosis there is extravasation of blood. Fourth following extravasation there is a discoloration of tissues and pigmentation.

The many and varied opinions expressed show that the etiology is unknown. I have very briefly gone over some of the literature on this subject to show the wide variance of opinion concerning the cause.

Inasmuch as we do not know the cause of this disease we are compelled to treat the condition. I believe the blood-count to be the first and most important initial step to be

undertaken in the treatment because if this condition is produced by a lack of certain elements of the blood these may be artificially supplied. This technique proved to be of great benefit to me in the particular case which I report.

I wish here to endorse the blood transfusion method as given by Richard Lewisohn in the *American Journal of Surgery* under date of October 1915. By this method the entire blood is injected direct from donor to recipient. A cannula is inserted into the vein and a 20 ccm. syringe filled direct from donor and injected direct into recipient. As large a quantity as is desired may be injected. The technique is the simplest of any blood transfusion operation I know of. It is not however without danger to the recipient. If too much blood is injected or it is injected too rapidly acute dilatation of the right heart may result. There is also danger of injecting too much air. A small quantity of air can be taken care of but a large quantity is extremely dangerous.

Purpura hemorrhagica is found most frequently in women.

In reporting my case I wish to emphasize the importance of family history as not infrequently we discover other members of the family to have been likewise afflicted.

A woman, age 34, father 65 and in good health, mother died at the age of 54 of cerebral hemorrhage, two brothers and three sisters are living and in good health.

As far as I am able to learn none of the ancestors was ever affected with this disease. When the patient was 3 she noticed a few spots on her limbs. These were at that time diagnosed as ring worms, *trichinella*. She has two children six and nine years of age. Both confinements, hard forceps deliveries. Was lacerated both times but repaired. Never has had any miscarriages. She began to menstruate at thirteen and has always been regular. Menstruation seemed normal as to time and quantity until about two years after the birth of the second child, then she noticed flowing was excessive and it lasted six or seven days.

Purpuric spots would appear on different portions of her body last a few days, and then disappear.

She did not consult a doctor until 1913 when she moved to Syracuse and consulted me regarding fallen arches. At this time no mention was made of any purpura spots or menstrual trouble. February 1914 she had acute appendicitis. I removed large acutely inflamed appendix which was glued to the

top to the ileum. Recovery was rapid and she returned home from the Homeopathic Hospital in two weeks. During or following the operation no trouble was experienced from hemorrhage, neither did any purpuric spots appear.

September 9, 1914, I was again called because of menorrhoea. The menses had at that time lasted eight days and the flowing was increasing in stead of abating. I was at first suspicious of miscarriage or if not that uterine polypus or fibroid. History and examinations revealed nothing and I was at a loss to account for the continued flowing. Doctor W. A. Groat was called to make a blood count and examination which was: Red blood-cells 4,000,000 coagulable decidedly retarded hemoglobin 40 per cent leucocytes 6,000.

There was profound secondary anemia with great reduction of blood platelets. Ergot and pituitrin had been given to assist in controlling hemorrhage with no effect. With the knowledge that the coagulating power of the blood was so greatly reduced horse serum was injected 10 ccm. every day for two weeks. After a few days the flowing began to decrease in quantity. Menstruation however continued for one period into another and finally stopped entirely before the third period. The administration of horse serum hypodermically was continued before and during the ensuing menstruation, the marked benefit in the condition of the blood and appearance of the patient. During the entire sickness, purpuric spots would appear in different parts of her body, these spots varying in size and appearance. They would appear generally one week following menstruation. At first the spots would be the small petechiae found scattered over her neck and arms. These would last several days, then the large ecchymotic patch could appear in different parts. There seemed to be no particular place where they would appear. These would last like any black and blue spot and then gradually fade away. The patient's habits of life were regulated, and proper hygienic instructions were given besides, general tonic treatment and the hypodermic use of iron citrate, etc. There was great improvement in the general condition. She could go and do as she pleased and enjoyed life in general.

April 8, 1915 the menses appeared as usual but the flowing was greatly increased. Vaginal examination revealed an erosion on the scar of the former laceration from which the blood was streaming. Local treatment was instituted to stop the hemorrhage. Silver nitrate 5 per cent solution was applied followed by packing with gauze saturated in 1:1,000 adrenalin solution. The horse serum was injected every day still I could see no alleviation of the symptoms.

Doctor Groat at this time made another blood examination as follows: Pale hemoglobin 30 per cent erythrocytes 600,000 coagulation decidedly retarded color index 0.8 leucocytes 5,400 secondary anemia.

The comparison of the last blood count with the first shows the same serious secondary anemia but to a much greater degree. It also revealed the fact that she was nearly exsanguinated. Her skin was as white as the sheets of her bed, the mucous membranes of her mouth and lips were as white as her skin. The case now assumed very alarming proportions. She was in a condition of shock most of the time, had breath hanging, then she would feel faint. Her body and face were covered with cold perspiration.

At the suggestion of Dr. Meader, coagulase was tried, still the flowing continued. She was literally bleeding to death. At this stage eight ounces of human blood was obtained from her husband and injected. This seemed to modify the serious symptoms a great deal. The flowing continued irrespective of treatment. Operative interference was advised against, still I could see this continual hemorrhage coming from the erosion on the cervix. Operation was decided upon and the uterine arteries were tied off followed by curettage. The hemorrhage was rather severe, but after the application of pure carbolic acid it flowed immediately with application of alcohol the uterus packed with gauze saturated in a solution of adrenalin 1:1000 the hemorrhage ceased. The operation was very well borne.

Human blood serum was injected as often as I could obtain same from husband. Scrapings of uterus were sent to Professor Steensland of Syracuse Medical College for pathological examination as I felt possibly malignancy might have some bearing on the case. Professor Steensland reported the condition innocent.

Following this operation which was performed at the patient's home, purpuric spots covered her whole body and lined the mucous membrane of her mouth, nose and throat, also many hemorrhagic spots appeared in the vagina. During this time she had frequent nose bleeds which were very difficult to control, also if she would brush her teeth especially hard so as to erode a small particle around a tooth, this would bleed perhaps twelve or twenty-four hours.

The cervix presented such a large stellate laceration that in my opinion it would very soon undergo degenerative changes and I considered this to be one of the chief causes of the menorrhoea.

I decided to amputate as soon as the condition of the patient warranted.

June 16 patient was removed to the Homoeopathic Hospital and on June 17 I amputated the cervix. Convalescence was untroubled and she returned home in two weeks. The menses appeared every twenty-eight days at first and were rather

prolonged and excessive, lasting about ten days. The condition has materially improved until now the entire duration is five days. One week following the cessation of menses small petechiae appear on different parts of her body. There is no pain or tenderness, no symptom of feeling weak and no inconvenience of any kind. The spot last a few days and then disappear.

She has gained in weight, weighing 140 pounds and looks the picture of health. She is able to go and do all the house. Examinations of the blood still show slight anemia with some reduction of blood platelets.

Purpuric spots also appear, they have before but the quantity is much smaller. The treatment now consists of proper hygiene and intravenous use of iron.

I have every reason to believe that this case will entirely recover, improvement has been so great and is steadily progressing.

To summarize: The laceration of the cervix in this case produced a subinvolution of the uterus, thus predisposing to increased and prolonged flowing and reducing the quality and quantity of the blood as a whole. The condition lasting over several years produced vascular disease. The vascular change seemed to have affected the power of the blood to coagulate at the proper time. Blood examination shows that it is the lack of blood platelets that produce the condition. The vascular disease is given by some writers as the first and primary cause of the disease. Constituents of the blood were taken away from time to time faster than the forming elements could supply them. Resulting from this we have a slowing of the blood stream and finally stasis with the formation of thrombosis and pigmentation.

The appearance of the petechiae and ecchymotic patches following menstruation show that at that time the coagulation power of the blood is at its lowest point, consequently I believe the treatment at this particular time should be to supply if possible the loss of blood by the direct transfusion method, namely the method of Richard Lewisohn alluded to in the early part of this paper.

THE RELATION OF THE ENDOMETRIUM AND OVARY TO HÆMORRHAGE FROM MYOMATOUS UTERI¹

By SAMUEL H. GEIST M.D. New York
From the Pathological Laboratory of the Mount Sinai Hospital

THE commonest and perhaps the most important symptom associated with uterine fibromyomata is undoubtedly hæmorrhage either in the form of menorrhagia or metrorrhagia. It has been the aim of many investigators to arrive at some definite explanation to account for this hæmorrhage but as yet no conclusive evidence in support of the various theories has been advanced. Hyperplastic changes in the endometrium have been noted as a common occurrence associated with bleeding and fibroids and consequently these conditions have been correlated by some authors. Others have attempted to link the hæmorrhage with inflammatory changes either in the endometrium or in the wall of the uterus. As would seem natural, because of the size and situation of these tumors mechanical causes, as pressure or obstruction with dilatation of the vessels, have been assigned an important rôle in the etiology of the hæmorrhage. One important organ, however has been neglected, but in the light of recent contributions to the physiology of menstruation and of the demonstration of amenorrhœa produced by the X-ray in treating fibroids and other conditions, the definite part played by the ovaries in the causation of hæmorrhage must be emphasized.

A brief review of the more important literature illustrates the various theories that have been advanced and shows how little attention has been directed to the study of the ovary as a possible etiological factor.

Von Campe (1) studied sixteen cases of fibromyomata, and found hypertrophy of the endometrium which he believed to be due to the presence of the tumor. Wyder (2) in an examination of twenty cases of fibromyomata noted the frequency of the endometrial hypertrophy and believing it to be inflammatory called it endometritis glandularis. He believed that this change in the mucosa had no relation to the hæmorrhage. He found

in those cases in which there was a concomitant hæmorrhage that an interstitial inflammation was present and suggested that the inflammatory condition was the cause of the hæmorrhage as well as the cause of the hypertrophy of the mucosa. His pictures, however do not show a true interstitial inflammation.

In the cases investigated by Uter (3) the same hypertrophy of the mucosa was noted and for the first time was considered apart from the tumor proper. The idea was advanced that some external irritation the same that in the musculature causes a circumscribed connective tissue overgrowth, produces an overgrowth of the mucous membrane.

However to disprove that the tumor produced the endometrial overgrowth, Cornil (4) demonstrated that the hypertrophic change was more commonly associated with small than with large myomata.

In an attempt to ascertain if the situation of the tumor had any effect on the mucosa, Schmal (5) analyzed fifteen cases and found that in subserous tumors the mucous membrane may be normal or hypertrophied while in the interstitial and submucous ones the endometrium over the tumor usually is atrophic elsewhere it is hypertrophic.

Semb (6) from a careful examination of fibroid tumors considering especially their situation the type of mucosa and the amount of hæmorrhage concludes that the commonest change in the mucosa associated with fibromyomata is hyperplasia. There may however be changes of a secondary nature such as inflammation or atrophy from pressure. He believes also that the hypertrophy of the uterine walls and vessels and the pressure of the tumor on the veins may cause the hæmorrhage.

With the work of Hiltachman and Adler (11) on the cyclical changes in the mucosa, it was necessary to study the effect of the

tumor formation on the normal menstrual cycle. Frankl (1) was the first to investigate the endometrial changes in myomatous uterus in relation to the normal menstrual phases. In the subserous and pure interstitial types of tumor he found that there were no changes in the endometrium that could not be included in the normal menstrual rhythm. In only one case was there a hyperplasia of the mucosa with rather marked oedema which latter condition was believed to be due to mechanical interference with the circulation. The interstitial tumor with a tendency to grow toward the endometrium showed abnormal variation in the cycle and the growing toward the mucosa likewise did not disturb the normal phases. In numerous instances he found a moderate thickening of the mucosa due to oedema and in other instances where the tumor projected into the uterine cavity he found pressure atrophy of the endometrium.

Clark (8) examined a number of fibromatous uteri and studied especially the circulatory apparatus by means of injection experiment. He came to the conclusion that the situation of the tumor and its consequent mechanical interference with the circulation was the main factor in causing the atypical hæmorrhage.

An analysis of the foregoing work shows how at variance the different theories are. Most of the investigators however have found that the mucosa is often hypertrophic some attaching to this an etiological significance in relation to the hæmorrhage while others imply regard the hypertrophy as a coincidental finding.

While von Campe (11) believed that the hypertrophy was due to the presence of the tumor Cornil (4) was able to show that the size of the tumor had nothing to do with the hypertrophy and that the larger the tumor the less likely was one to find a hypertrophic mucosa. This seems to throw considerable doubt on the theory of von Campe.

Frankl's contention that the thickening of the mucosa is due to oedema is not borne out by histological examination microscopically one can see not only oedema and congestion but hyperplasia and hypertrophy of both the glandular elements and the cellular constit-

uents of the stroma. The conclusions of Clark that the hæmorrhage is due to a mechanical condition will be discussed later but we believe that this theory of mechanical obstruction is not the entire solution or even the most important factor.

In an attempt to correlate these various theories especially in the light of recent contributions to the physiology of menstruation and its relation to corpus luteum evolution I studied seventy five fibromatous uteri representing all types of tumors and presenting various symptoms. In all the cases the menstrual history was accurately investigated. In sixty cases the adnexa were also examined. Of the seventy five cases fifty gave a history of menorrhagia, some few also having metrorrhagia.

If we analyze the histological changes in these fifty cases we find that in thirty six or 72 per cent the mucous membrane of the uterus showed hypertrophy irrespective of the phase of the normal menstrual cycle. In one case the mucosa was not examined but an adenomatous polyp was present the glandular elements of which had the same charac-

teristics as those to be described as typical of the hypertrophic endometrial condition.

In three instances there was an atrophy of the mucosa associated with large tumors, due in all probability to pressure, and in ten instances the endometrium was in the resting or interval stage though in two of these it approached the hypertrophic picture. In other words the most common condition found in the mucosa in the bleeding cases is an hypertrophy.

A closer investigation of those cases that had abnormal bleeding and did not show the typical picture in the mucosa, is instructive. Of the thirteen cases that showed abnormal bleeding and did not present the usual hypertrophic mucosa, five showed a condition of slight hypertrophy and edema with some tortuosity and dilatation of the glands. In other words a mild attempt at the usual picture. Three cases had atrophic mucosa associated with large tumors. The atrophy however occurred over the tumors and on the uterine wall opposite them, where the question of pressure undoubtedly played a prominent part, while the mucosa between the tumors showed decided hypertrophy. Five cases presented the typical interval or resting mucosa. In these five cases we have no explanation to offer for the absence of the hypertrophy. An analysis of Table I will show how absolutely independent the mucosal change is of the situation of the tumor and also of its size.

Of the twenty five cases in which the

menstrual history was normal Table II illustrates the relation between the situation of the tumor the menstrual cycle and the condition of the mucosa.

In this group of cases we have but nine or 36 per cent that presented the hypertrophic change and fourteen or 56 per cent showing an interval stage. In two cases no examination was made of the mucosa there being present in these instances adenomatous polyps. Of the nine cases with normal menstrual histories in which the mucosa was hypertrophic one was menstruating on admission. Seven were operated upon at the time of the normal premenstruum. One a patient of 40 had amenorrhea for four months. Of this group only the last case cannot be explained as due to physiological causes.

In other words irrespective of the size and situation of the tumor in those cases giving a history of metrorrhagia or menorrhagia and irrespective of the phase of the menstrual cycle we find a markedly hypertrophic mucosa. It is not edema alone for all the elements of the endometrium take part in the change. The glands are tortuous distended often cystic and sometimes increased in number. The cells lining them are large with pale staining protoplasm and contain basal or centrally placed nuclei dark staining and oval in shape. The cell border toward the gland lumen is often raised in the form of a little cap or knob which is granular and when stained by selective dyes shows the same tinctorial characteristics as the secretion which is almost always found in the gland lumen.

The cells of the stroma are somewhat enlarged and pale the nucleus small round or oval deeply staining and centrally placed. Where there is much interstitial edema the cells are separated for a fair distance but in the absence of edema the cell bodies are barely distinguishable and the cells closely crowded together. There are no evidences of inflammatory reaction as a rule, though occasionally one may find inflammatory cells. Blood extravasations are found though not often. These are situated under the mucosa or in the interstitial tissue.

1 Normal premenstrual hypertrophy

The entire histological picture resembles very much the changes one finds in the mucosa during its normal premenstrual phase and it seems reasonable to suppose that the same stimulus—namely some ovarian activity is the cause of the hypertrophy found associated with fibroid. In the uterus from the cases of essential uterine hæmorrhage (Geist 10) we find a similar hypertrophy of the mucosa and this type of hæmorrhage is now generally conceded to be due to a disturbance of the balance of the endocrinous glands.

In an effort to ascertain if there were any definite lesion in the ovaries the ovaries in fifty-five cases were also carefully examined. In thirty-eight there was a history of bleeding and in seventeen the menstrual history was normal.

In considering the adnexal changes in relation to the bleeding and to the changes in the mucosa we are struck by the predominance of one type of lesion in the ovary, namely the persistence of a large corpus luteum which is occasionally cystic. In sixteen cases or sixty-two per cent of the twenty-six with hypertrophy of the endometrium we found this condition of persistent corpus luteum and only in three instances were the ovaries to be classified as absolutely

normal. In the nine cases in which the mucosa was in the resting stage only two showed this ovarian change and in one of them there was a slight hypertrophy of the endometrium.

Of the seventeen cases in which the menstrual history was normal only two showed the large corpora lutea and in these there was a premenstrual change in the mucosa.

An analysis of the foregoing cases shows that when the mucosa is hypertrophic and pathological bleeding is present the ovary is grossly abnormal presenting either cysts, inflammation or most commonly a large corpus luteum often cystic in character.

We have seen that in the majority of cases of uterine fibroids irrespective of their size or situation, when the condition is associated with pathological bleeding the mucosa presents a hypertrophic condition resembling that seen in the normal premenstrual phase of the menstrual cycle. The recent work of Ruge and Meyer (9) has shown that the normal premenstrual phases correspond in time to the height of development of the corpus luteum and that the hypertrophy of the mucosa is probably due to ovarian activity or more specifically to corpus luteum activity. We thus have reason to believe because of the resem-

Fig. 1. Menstrual phase. Fig. 2. Premenstrual phase. Fig. 3. Menstrual phase. Fig. 4. Premenstrual phase.

blan e between the two pictures is the mu a that the are stimulu perhaps perverted by the ause of the hypertrophy of the mu a in the fibril ase. In most of the ase where atrophy was found the nition will be ac counted for either by pressure of molar e tu mor or by anitis. In two of the ase where there had been pressure atrophy we found in the spaces between the tumor a hypertrophic condition which resembled that usually found in the bleeding cases. It is not possible to account for the change in the mucosa purely on the basis of a vascular obstruction for in cases with subperitoneal and small intramural tumor where there is no marked vascular obstruction we find the same hypertrophic change of the endometrium associated with pathological bleeding. Furthermore the change is not purely a passive edema and engorgement but is an active increase in size and sometimes in number of the glandular and stroma element.

Again in hybrid cases where a normal menstrual history is obtained we find the mucosa corresponding to the normal phase in the menstrual cycle while in other cases presenting tumor of the same size and situation in which atypical hemorrhage is the prom-

inent symptom the mu a in the great majority of instances is hypertrophic.

In the instances where we were led to expect the hypertrophic mu a it usually were embarrassed by finding a lining not in line. Usually there was an atrophy of the mu a which could be accounted for by pressure from large tumor and in a few instances localized hypertrophies in the form of polyp were encountered whose histological constituent closely resembled those of the hypertrophic mucosa commonly associated with the bleeding cases. We are led to suspect that in many instances of bleeding in which the only lesion found is a polyp the bleeding is really of ovarian origin and that the polyp represent a localized hypertrophy due to disturbed ovarian function. Because of the resemblance between the histological picture of the hypertrophic mu a associated with the bleeding and that normally present in the premenstrual phase which latter condition has been shown to depend on some ovarian function probably the corpus luteum we are led to believe that the change seen in the bleeding hybrid cases is an expression of disturbed ovarian function and that the bleeding and hypertrophic mu a

have a common or related etiological factor. In further support of this theory can be advanced the evidence of X ray therapy. It is established that the X ray treatment of bleeding fibroids quickly stops the hemorrhage long before the size or situation of the tumor is influenced. We also know that it is the ovary and more particularly the more mature follicles that are first affected by the ray and consequently feel justified in regarding not the tumor but the ovary as the important factor in the cause of the bleeding.

Supportive evidence pointing to the activity of the ovary as the source of the hemorrhage, is found in the clinical behavior of fibroids associated with pregnancy. The hemorrhage from fibroids during pregnancy in most instances, though the tumor in its size and situation remains unchanged ceases. The ovarian activity is to a great extent in abeyance during pregnancy and it seems that in view of the previous discussion we are justified in assigning the important rôle in causing the cessation of the hemorrhage to the functional inactivity of the ovary.

To summarize, we can say that in most of the cases of fibroid uteri associated with pathological bleeding we have a hypertrophic condition of the mucosa. The ovaries in these cases vary from the normal, there being present most often a large corpus luteum occasionally cystic. These findings seem to us very significant in view of the fact that

the ovarian influence is of primal importance in regulating the normal hemorrhage from the uterus and it seems reasonable to suggest as a possible etiological factor for the atypical hemorrhage associated with fibroids, disturbance in the function of the ovary perhaps of the corpus luteum.

I wish to thank Dr F S Mandlebaum, director of the laboratory for the privilege of studying the material and for the excellent photomicrographs which he made and also to express my appreciation to Dr J Brettauer and Dr F Krug for their kindness in allowing me the use of the clinical data.

(The photographs illustrate variations, from the normal picture as seen in the uterine endometrium associated with fibromyomata. The varieties pictured represent types of hypertrophies where one would normally expect a resting stage.)

SARCOMA OF THE SCAPULA HISTOLOGICAL DIAGNOSIS MADE BY STUDY OF BLOOD ASPIRATED FROM PULSATING PORTION OF THE TUMOR

By C. E. ROYCE, A.B. M.D. Iowa City, Iowa
Department of Pathology and Bacteriology, State University of Iowa

THE cytological study of the various exudates is a well recognized laboratory procedure and has a proved value in distinguishing between neoplasms and various types of inflammatory processes affecting the linings of the serous cavities. That a similar study of fluids

aspirated from tumor masses may have a like value seems possible from the instance I shall relate.

Among the specimens coming to the laboratory recently was ten cubic centimeters of fluid blood. The accompanying request card stated that the fluid had been aspirated

ROYCE SARCOMA OF THE SCAPULA

Fig 1 Photograph showing tumor of right hould

from a tumor of the houlder which was tentatively diagnosed as sarcoma and asked for the nature of the fluid. The fluid was allowed to stand over night at room temperature. The next morning it was clotted. Ten per cent formalin was added without disturbing the clot. The following day a portion of the clot was removed and imbedded in paraffin. Sections from this block stained with haematexin and eo in present beautiful pictures of island of sarcoma-cells imbedded in a matrix of fibrin and red cells. The cells are of the small round variety and mitotic figures are frequently seen.

The history shows the patient to be a white male 19 years of age single of good habits and without previous illness. The family history is irrelevant except for the vague statement that his mother died of a tumor of the stomach. He complains of pain and swelling of the right houlder. The duration of

Fig 2 Roentgenogram showing cavity formation with in the tumor

the tumor covers four years and date to an injury of the houlder while coasting. The growth has been slow but there has always been more or less pain.

UNILATERAL HÆMATURIA ASSOCIATED WITH FIBROSIS AND MULTIPLE MICROSCOPIC CALCULI OF THE RENAL PAPILLÆ

B. R. L. PAYNE, J. M. D. FACS, N. BOLA, VIRGINIA

DURING the past decade there have been many articles written on unilateral hæmaturia and like all other unsolved pathological problems, there have been quite a diversity of opinions expressed.

At the meeting of this society in 1912 the writer presented a paper¹ setting forth a résumé of the various pathological interpretations published up to that date and related a series of experiments which helped to eliminate the acutely developing vascular lesions as a causative factor of unilateral renal hæmorrhage.

A large number of careful observers have reported the evidences of chronic inflammation in sections of kidney tissue removed from the type of case under consideration and our studies of personal cases before and since 1912 have confirmed the belief that chronic

inflammatory changes are the principal factor in the production of unilateral hæmaturia.

We also advanced the theory in the paper above mentioned that chronic inflammatory changes raise the local vascular tension to the point where rupture of the capillaries occurs with a resulting hæmorrhage.

The following case is presented not with the idea of drawing therefrom any definite deductions but for the purpose of explaining and defining our interpretation of the pathology present in this particular case.

C. H. J. male, age 70 occupation, school-teacher family past and social history negative. Present history—Seven years ago he first observed the presence of blood in the urine. This occurred at varying intervals until three years ago since which time there has been blood continuously present in the urine.

The patient has never suffered a particle of colic or pain, nor has there been associated any spells of fever. The amount of urine passed has always

Fig. Camera lucida drawing. Leitz obj. 6, oc. Three calculi are shown surrounded by proliferation of connective tissue. At *b* are seen dilated capillaries packed with blood-cells. *c*, A papillary duct cut in its long axis.

Fig. Camera lucida drawing. Leitz obj. /6 oc. Taken from section through the apex of renal pyramid. At the enormously dilated venous spaces are seen. The connective-tissue overgrowth at *b* is marked. At *c* is seen papillary duct cut in its long axis.

Fig. 3. Microphotograph X 88. Section through tip of papilla. On free surface is seen a ruptured capillary which still contains some blood cells. T cells are also shown.

Fig. 4. Microphotograph X 15 (taken from same section as Fig. 3) shows five calculi, numerous dilated capillaries, and considerable connective tissue overgrowth.

been plentiful but the patient gives the history of persistent constipation. There had been a perceptible loss of weight and the patient looked very anemic. On physical examination neither kidney was palpable and there was no tenderness over either loin space. X-ray examination was negative for stone and the microscope revealed an abundance of blood in the urine but no pus, no crystals and no casts.

Cystoscopic examination showed a normal bladder with bloody urine spurting from the right ureter and clear urine from the left side. No resistance was met with either ureteral catheter but the separate specimen showed with the microscope clear urine from the left kidney and bloody urine from the right side. Functional phthalein tests showed a normal output from the left side and a marked reduction from the right kidney. Bacteriological studies of the separate specimens was negative from the left kidney but showed a few colon bacilli from the right kidney.

Bacteriological study of the bladder specimen also showed the presence of colon bacilli.

Operation was decided upon because the writer has observed several of these cases relieved by section of the kidney from pole to pole and down to the pelvis in the absence of any demonstrable lesion to the naked eye.

At operation the kidney seemed normal in appear-

ance and size and no stone or new growth could be demonstrated. Upon bisection the cortex and parenchyma showed nothing definite but every single papilla was intensely congested and the tip of every papilla presented a cherry red appearance which coincided macroscopically with the classical description of an angioma.

The writer had never before done a nephrectomy for this condition but it did not seem reasonable that bisection with suture could relieve this particular case nor did it seem possible that the experience of Fenwick¹ could be applied to multiple angiomas of every papilla.

Keeping in mind the normal functional test of the left kidney, nephrectomy was accordingly done and herewith is appended the pathological report by Dr. Wm. DeB. MacNider of the University of North Carolina.

Gross appearance. Kidney in 10 per cent formalin is 4 $\frac{1}{2}$ x 3 x 1 $\frac{1}{2}$ inches. The capsule is easily removed, not adherent and the surface is smooth and normal in color. The cut surface shows a normal relation of cortex and medulla.

The cortex is uniformly pale. All of the pyramids appear congested. This congestion macroscopically takes the form of streaks running in the long axis of the pyramids. In several instances these streaks lead to areas of congested reddish

Fig 5. Microphotograph, X55 showing large section of papilla with ruptured capillary and much hemorrhage on free surface. Also large number of dilated sinuses scattered throughout section.

brown in color which surround and cap the apices of the pyramids. All of the renal papillae show marked congestion.

Microscopic pathology There is no increase in intertubular connective tissue and no adhesions of the vessels. The glomeruli do not show any increase in capsular connective tissue. There is, however, quite a uniform increase in connective tissue cells between the capillary loops of the glomeruli. This connective-tissue change is likely of recent development because connective tissue fibers have not been laid down.

The capillaries in this area are intact, hence, there is no evidence of the hematocrit having originated from a ruptured capillary loop or loops. The epithelium of the cortex appears normal. The tubules in the cortex occasionally contain granular material which shows an absence of red blood-cells.

Sections were made passing through the papillae and pyramids both in the long axis of the pyramids and at right angles to this axis. Such sections show the epithelium of the tubules in this zone of the kidney to be fairly normal. In the region of the papillae there is a distinct increase in intertubular connective tissue. This increase is not uniform in its distribution.

Located in the region of the papillae and principally between the tubules but rarely inside a tubule are numerous calculi which are microscopic

Fig 6. Microphotograph, X8 of same section as Fig 5 showing the dilated and ruptured capillary containing few red cells and abundant hemorrhage on the surface of the papillae.

In size. Surrounding and in the region of such concretions there is an unusual overgrowth of connective tissue. In this connective tissue, usually between the tubules, the small veins and capillaries are hugely dilated into venous sinuses.

Many of the small calculi lie in close apposition to these vascular sinuses. Such sinuses are well filled with blood. In such cases the tubules may be compressed by either the dilated capillaries or the intertubular calculi.

All of the papillae show dilated capillaries. Net work on the surface many of which were ruptured with free blood escape. These were the small varicosities were evident in the surface of the hemorrhage.

The origin of these varicosities is not clear. It would seem, however, that the numerous though small calculi added by the connective tissue they had originated, succeeded in causing an obstruction to the venous return and a subsequent dilatation of the capillaries with resulting varicosities.

The writer does not believe that deductions can be drawn from one case. The facts here presented would, however, lend weight to the theory of those who believe chronic

inflammation to be the cause of unilateral renal hæmorrhage

Briefly to summarize we have a case of so-called essential hæmaturia which flows in the kidney removed that macroscopically the only part of the organ involved in a pathological process is the papillary area

Microscopically the cortex and medullary portion is pathologically negative while the papilla show definite lesion as follow

(1) Numerous microscopical calculi (2) overgrowth of connective tissue (3) hugely dilated capillaries (4) calculi lying in close apposition to dilated capillaries (5) dilated capillaries in a net work on the free surface of papillæ many of which are ruptured with free blood escaping

It is not the part of this paper to discuss the question of infection hæmatogenous or otherwise whether the stones were the beginning of the process whether the connective-tissue overgrowth was the cause of the varicosities or in any way to theorize concerning the causative factors involved but to report accurately our findings and partly show them in the accompanying illustrations

Finally after five years of study of so-called essential unilateral hæmaturia both clinical and experimental together with an intimate knowledge of the literature this is the first instance known to us where the definite

Fig. Mic. phot. graph No. 152. Section through tip of papilla showing a dilated capillary cut in its long axis. It was filled with blood but ruptured on the free border of the papilla

source of the hæmorrhage and the probable cause thereof in a case of symptomless unilateral renal hæmorrhage is shown

THE PROCESS OF REPAIR IN WOUNDS OF THE SMALL INTESTINE

B JOHN E. McWHORTER, M.D. A. P. STOUT, M.D. AND CHARLES C. LILL, M.D. NEW YORK

IN accordance with a general scheme suggested by the Director of the Surgical Laboratory to study the phases of repair in the body systems we have selected the problem of repair in the gastro-intestinal tract with the hope that data might be obtained that would be of practical value in the post-operative care of intestinal suture. The small intestine was chosen first because the undergraduate course in operative technique afforded abundant material. Later we hope to supplement this work with similar observations on the large intestine and stomach.

The objects of these experiments are *first* the determination of the hydrostatic pressure that a repairing intestinal wound will withstand *second* the effect of transverse division and suture on segmentation and *third* an observation of the gross and microscopic phenomena of repair.

HISTORY

In 1887 Senn (1) described experiments on the production of obstruction, volvulus, strangulation and intussusception together with the results obtained from resection and subsequent suture of the intestine. During the course of his experiments he reported, though not in detail, a few of the processes of repair. In one series of experiments he produced obstruction by tying the intestine near the ileocecal valve. Three to seven days later he performed an ileo-ileostomy or ileocolostomy using decalcified bone plates. One of his dogs died at the end of 24 hours. When the intestine was subjected to hydrostatic pressure no leakage occurred at the site of suture. He believed that absolute physiological rest of the intestine was necessary for perfect healing. He also reported that scarification or chemical irritation of the peritoneum produced adhesions that were both firmer and more rapid in their development than those following simple apposition of serous surfaces by suture. After mechanical or chemical irritation of the peritoneum

an outflow of blood and lymph appeared on the surface. He also noted that gross vascularization began after 40 hours. At 15 days the mucosa was almost but not quite completely regenerated.

In 1896 Mall (2) presented a detailed picture of intestinal repair. He noted that within a few hours after the suture the serous surfaces were adherent and he believed that fibrinous union took place before the operation was completed. At the end of 24 hours the inverted cut edges of the intestine showed extensive coagulation necrosis. After 48 hours in the sulci between dead and living mucosa epithelial cells of embryonic type were proliferating in all directions. At the end of 6 days there was a downgrowth of glands into the submucosa, probably because the needle tore through the bottom of the crypts. Many of these glands were cystic. At the end of 14 days the approximated layers of the muscular and submucous coats were united by firm fibrous tissue. The denuded surfaces of the mucosa were covered with granulation tissue until the crypts and villi had regenerated. On the fifteenth day the mucosa was almost completely regenerated. After 24 days regeneration was complete. When the mucosa had healed the inverted parts unfolded and the intestinal wall straightened out into a smooth unbroken line. At the end of two months, all the coats were fully regenerated.

He divided the processes of healing into four stages: *first* the immediate fibrinous union of the serous surfaces; *second* the destruction of the parts protruding between the flaps of mucosa; *third* the regeneration of the mucous membrane; *fourth* the straightening out of the suture line.

Gould (3) confirmed most of Mall's findings, but noted in addition that the plastic exudate uniting the serous surfaces extended from 3 to 5 cm. beyond the line of suture. At the end of three days some 3 to 5 mm. of fatally injured mucosa had sloughed and the submucosa was edematous. Many new

Diagram 1. Intestine

connective tissue cell appeared in the clot between the approximated serous surfaces and complete organization took place at the end of the eighth day. In one case he found that the denuded surface was covered with embryonic epithelium at the end of eight days. After 21 days the denuded area was completely covered by the newly formed mucosa but the muscularis mucosae had not developed. The muscularis was approximated by the contraction of the intervening scar tissue.

According to von Frey (4) a plastic exudate glued together the approximated serous surfaces of the sutured intestine. He made no direct statement relative to muscular regeneration although in his drawings of sections taken two days to four months after operation the muscularis had not regenerated.

Hoffman (5) showed that small defects in the mucous membrane of the stomach and intestine of dog healed completely. A defect of 1 by 1 cm had regenerated completely at the end of 32 days excepting for a small area about 4 mm in diameter. Larger defects were covered with a single layer of epithelium while very large defects were covered with granulation tissue.

Meek (6) reported that the longitudinal muscular coat of the cat's intestine regenerated in from 7 to 9 days after division and suture.

Cannon (7) in a discussion of the relative merits of end-to-end and lateral anastomosis gives his results from observations made on different animals one, four, seven and ten days after end-to-end union of the intestine. He found that in no case was the slightest evidence observed of stasis of the food in the region of the operation. In lateral anastomoses however he found at the end of ten days to two weeks a more or less complete blocking of the canal by accumulated hair and undigested detritus at the opening between the apposed loops.

TECHNIQUE OF OPERATIONS

The experiments were divided into two series: one upon the relatively normal small intestine and the other upon an intestine that had been previously injured.

Series 1. The animals in this series were dogs of various types, unselected and often poorly nourished. The operations were done by fourth year students who had had little if any previous operative experience. Each

Fig. 4. Movement of circular coat of intestine one hour after end-to-end anastomosis. Upper tracing made by circular coat 95 mm. caudal to anastomosis. Lower tracing made by circular coat 5 mm. cephalad to suture. During contraction of the muscle lever moves upward. Lowest tracing three in minutes. Note change in speed of kymograph.

operation was supervised by an instructor who however did no part of the operation. There were three varieties of operations on the small intestine: the repair of enterotomies, lateral anastomoses, and end-to-end anastomoses. The method of suture varied somewhat, but as a rule an inner layer of through-and-through continuous or lock stitch was taken and this was infolded by some form of continuous seromuscular suture. The suture material was invariably white silk. Since the course is particularly designed to teach operating room asepsis, special care was taken to maintain as perfect a technique as possible. All the operations of exposing the lumen of the gut were done with a change of towels and instruments between the middle contaminated and the terminal clean stages.

The care of the dogs was as follows. The day before the operation the dogs were given a soap and water bath and the field of operation was cleansed of hair with barium sulphide mixture. All the operations were done in the forenoon and on that day the dogs received no food at all. The anæsthetic used in every case was ether. Following all operations the dogs were given as a routine water on the day of operation, milk and water the next day, and regular diet of bread, meat, and small bones on all succeeding days.

Series B. After completing the first series the objection was raised that the experiments were inconclusive since the operations were done on the normal intestine. Consequently we endeavoured to injure the gut by interfering with its blood supply before doing the suture operation. Some difficulty was encountered before a satisfactory method was found. Ligation of the mesentery which included the vessels supplying a loop of intestine a foot in length had apparently no effect on the viability of the gut. Injecting liquid paraffin into a branch of the mesenteric artery or vein was a little more successful but could not be controlled. Sometimes a loop became moderately hyperæmic but more often there was no effect at all or there was a general mesenteric thrombosis with gangrene and quick death. Finally a simple effective and easily controlled method was devised: a piece of half inch tape was tied about a loop of intestine just tight enough to cut off the venous return while still allowing the entrance of arterial blood. This simulates strangulation of the gut as seen in strangulated hernia, volvulus and like conditions. This preliminary operation was done twenty-four hours before the second operation which consisted of wide resection of the strangulated gut and end-to-end anastomosis. In this second series the preliminary operation was done by the experimenters and the resections and anastomoses were done in some cases by students, in others by the experimenters themselves. The method of anastomoses was that already described.

HYDROSTATIC EXPERIMENTS

Technique of experiments. The specimens of both series were handled in exactly the same way. The dog was killed or died at periods from 25 minutes to 144 days following the suture operations. The abdominal cavity was opened as soon as possible after death and a loop of gut was excised which included the area of operation and six inches or more on each side of it. This segment was then treated in either one of two ways. Some had one end tied off and a glass syringe fastened into the lumen at the other. Water was then introduced until the loop was considerably

distended. During the distention the suture line was under observation for leakage.

The other specimen were subjected to measured pressures as follows. After removal from the body the specimen was immersed in warm Ringer solution and glass cannulae were inserted into the lumen at either end and securely tied in place. While the gut was still submerged both ends were connected to the apparatus by means of rubber tubing. One of the connected ends (Fig. 1 a) led to a water bottle (Fig. 1 b) containing colored Ringer solution. This bottle was hung from the ceiling and by means of a rope and pulley could be raised and lowered to any desired height thus giving various hydrostatic pressure. The rubber tubing at the other end (Fig. 1 c) was attached to the short arm of the water manometer (Fig. 1 d). With the

intestine connected to the apparatus the air was expelled from the lumen of the intestine as well as from the various lengths of tubing by raising the water bottle A by pass (Fig. 1 e) with stop-cock in front of the manometer allowed for the escape of air without the disturbance of fluid level in the manometer tubes. Next the water bottle was brought to the level of the intestine and the stop cock was opened. The level of the fluid in the long arm (Fig. 1 o) of the manometer was noted and marked zero particular care being taken to see that this point did not represent either negative or positive pressure.

To obtain positive pressure within the lumen the water bottle was gradually raised to any desired height and the pressures were calculated by measuring the height to which the fluid rose in the long arm. Any leakage

Fig. 3. End-to-end enterostomy 14 hours. Surgical Pathology V 34. A Sutures between lumen mucosa and unfolded cut edges of intestinal coat. B newly formed epithelial line.

was at once detected for the Ringer's solution in the water bottle was colored blue with *acridin blue* a vital stain.

Results of the hydrostatic experiments. As may be seen by referring to Tables I and II thirty two specimens in Series A and B were subjected to various degrees of hydrostatic pressure from within the lumen. As the results in the two series were the same they will be considered together. Six leaked. Of the twenty six that showed no leakage nineteen followed suture of supposedly normal gut while seven followed resection of gut showing more or less severe vascular changes. The experiments were done at from twenty five minutes to 144 days following the suture operations. The measured pressures which the specimens withstood without leakage varied from 350 to 1400 mm. of water (one-

half to two pounds per square inch). That these pressures far exceed any that under ordinary circumstances exist within the living intestinal lumen may be readily appreciated by considering for a moment the normally functioning intestine.

The actual amount of positive pressure in the intestinal lumen *in vivo* is unknown. The pressure varies considerably even under normal conditions for during the intervals of digestion when the intestine is quiescent, the pressure is practically zero. During digestion however with the passage of the bolus along the canal the internal pressure at any one time and upon any given area is certainly positive but the actual amount is relatively slight. Even under abnormal conditions of distention although the pressure is undoubtedly far greater than the average it

unquestionably never approaches anywhere near the amount to which the above tubulated specimens have been subjected.

Willis Andrews (8) working with ox intestine and human intestine freshly removed from the body found that they burst at an internal air pressure of from 6 to 10 pounds per square inch. Senn (8) experimenting on the cadaver in a case of enteritis found that the diseased bowel ruptured at an air pressure of $1\frac{1}{2}$ pounds per square inch.

Muller (9) in a recent article on the bursting strength of the alimentary tract found that in cats the average pressure necessary to rupture the jejunum was 28.2 pounds per square inch (1458 mm Hg) and the ileum was 4.8 pounds per square inch (1254 mm Hg). This pressure varied considerably in different cats but was uniform in the same individual. He further noted that the tear was linear and ran in the long axis of the organ and that the strength of the alimentary tract lay chiefly in the submucosa.

The six cases of leakage above recorded together with a number of similar cases examined but not included in the tables were with the exception of one case invariably

associated with local infection about the suture line or a general peritoneal infection. The one exception was that of a lateral anastomosis done by one of the students (Table I No. 1) and tested twenty-five minutes after completion of the suture operation and fifteen minutes after the death of the dog from the anesthetic. The leakage here was due undoubtedly to faulty operative technique. What the source of the infection was in the other cases could not be definitely ascertained. In many a visible hole leading into the lumen was present and in these cases the leak probably preceded and caused the infection. That other lesions without infection can be present in the intestinal tract without interfering with the repair is seen from cases seven and fourteen of Series A (Table I). These dogs died respectively of mesenteric thrombosis and intussusception and yet showed a resistant suture line. That very slight local infection is of no consequence is amply proved by the relatively enormous pressure that some of these specimens withstood though the microscopic picture was that of infection. Given however a marked infection whether accompanied by gross

Fig. 5. Enterorrhaphy sixty day after operation Surgical Pathology \ 39 showing complete regeneration of mucous membrane and realignment of muscular coat

suppuration or not leakage will take place at pressures so slight that they cannot be recorded by the manometer

In connection with this work on the living intestine it is of interest to note the two following experiments. A dog was chloroformed and at death the small intestine was divided in two places and immediately joined by end-to-end anastomosis. One half hour later one of these sections was removed and subjected to pressure of 850 mm. of water without leakage. Two hours later the second section was excised and subjected to a pressure of 1250 mm without evidence of leakage

VIABILITY OF THE INTESTINE

It has been shown in a previous section that an Intestine can withstand within one hour after an anastomosis an internal pressure varying between 330 mm and 1400 mm of water. It seemed worth while to determine whether such operations as anastomoses interfered with the viability of the gut.

No better index of the viability can be

offered than a graphic record of the movements of a loop of intestine which includes an anastomotic suture. A preliminary experiment with a loop of dog's intestine one hour after the repair of an enterotomy showed that this operation did not interfere with the contractions of the longitudinal muscular coat. Such an experiment would not indicate whether the contractions were due to movements of muscle fibers in close proximity to the injury or to those fibers at a considerable distance from the site of operation

In order to determine the relative activity of smooth muscle near the site of operation and at a considerable distance therefrom the following experiments were devised

Immediately after the suture had been tested for its efficiency against internal pressure the cannule which had been tied into the lumen were removed and the loop of intestine was transferred to an oblong dish containing fresh, warm Ringer's solution. The loop of Intestine was then fixed by means of two sutures to a glass tube the ends of which were

bent at right angles. Exactly opposite the two original sutures two other stitches were taken and tied. One end of each of these threads was then passed over a pulley and connected to a recording lever which wrote upon the smoked paper of a slowly moving kymograph. The levers were properly weighted and wrote in such a fashion that when the circular muscle of the intestinal loop contracted the writing point moved upward; during the relaxation of the intestinal wall the writing point descended. Oxygen was supplied to the Ringer's solution which bathed the intestinal loop and the temperature of this solution was maintained at 38 to 39° C by means of a large water bath.

The position of the sutures varied in the different experiments so that we were able to study muscle within 5 mm of the site of operation as well as muscle 100 mm from the

line of suture. The accompanying illustration (Fig. 1A) is a graphic record made by the circular muscle of a loop of intestine which was excised one hour after an end-to-end anastomosis had been made. The lower tracing is made by the circular coat 15 mm cephalad to the suture; the upper tracing represents the movements of the circular coat 95 mm caudal to the anastomosis. The movements of the muscle 95 mm from the site of injury are powerful, regular and show very distinct tonus waves. The movements 15 mm from the injury are fairly regular and show less pronounced variations in tonus.

Though it is true that all the movements that we have recorded are comparatively small this may be accounted for first by the fact that these loops have invariably been exposed to a very high internal pressure and second to the fact that the dogs have received

TABLE II

The times given above refer to the time elapsing between the second operation and the death of the animal. The second operation in every case in this series was an end-to-end anastomosis. Twenty-hour hours elapsed between the first and second operation in every case except experiment N 4, where only six hours intervened. The pressure in every case was measured by the water manometer.

no food for 12 hours previous to operation. This latter element is probably the more important since Magnus has shown that an animal recently fed shows very much better intestinal contractions than one that has been fasted.

In all the experiments the movements of the gut which are carried out in close proximity to the site of injury are invariably smaller than those made by the intestine 10 or 20 times more distant.

The interval elapsing between the time of operation of anastomosis and the graphic recording of the movements does not modify the strength of the contractions. Thus, in experiments which have been carried out in a dog killed one hour after anastomosis the contractions are no larger than in experiments that have been made four days after a similar operation. A moderate amount of acute inflammation about the suture line does not interfere with the movements of the muscle, either near the suture or at a considerable distance from it thus in one experiment the contractions made by a ring of muscle 5 mm from the suture were quite as well defined as those made 150 mm from the suture line.

Only one experiment was carried out on an intestine after gangrene had been produced. In this particular instance, muscle 60 mm from the suture line contracted well, whereas muscle 5 and 15 mm from the suture line remained absolutely quiescent. This quies-

cence cephalad to the injured area would seem to be a protective mechanism. It has been shown that when gangrene occurs the suture line does not withstand an increase in internal pressure. Normal movements of the intestine are undoubtedly associated with an increase in internal pressure. And if weakness occurs at the line of suture an escape of intestinal contents into the peritoneal cavity will occur. From these experiments then it appears that the inhibition of the intestine cephalad to the suture aids in preventing the escape of intestinal contents into the peritoneal cavity.

The movements which have been recorded are not true peristaltic movements. They represent only the segmenting movements of Cannon. No attempt has been made to record graphically true peristaltic contractions. Careful observation has never shown a peristaltic wave spread across the suture line.

The conclusion that may be drawn from these experiments is that despite the very severe operation the smooth muscle of the intestine retains its viability and its segmenting function. This function is demonstrable within one hour after the completion of the operation and is present four days after operation. In the presence of gangrene and a leaking suture, these segmenting movements are inhibited cephalad to the suture whereas caudad thereto the movements are regular, powerful, and well-defined.

ANATOMICAL AND HISTOLOGICAL OBSERVATIONS ON THE PROCESSES OF REPAIR AND REGENERATION

From a gross and microscopic examination of the thirty two specimens comprising the two series together with an examination of many similar suture operations done in this laboratory and a comparison of these observations with those of Mall Gould and others a fairly comprehensive picture of repair and regeneration in healing intestinal wounds has been obtained.

In the course of an operation that divides and then sutures the coats of an intestine a certain amount of damage is done. The knife that has severed the intestinal coats and the scissors that have trimmed off the redundant mucous membrane have killed many cells and fatally injured many more. Handling the peritoneum has done some damage to its serous cells. The needle while passing through the wall of the gut injures some of the small blood vessels. It may also tear off the bottoms of some of the glands and ruptures of the mucosa and may even carry living epithelial cells along the suture tract deep into the submucosa or muscularis. Finally slight contamination of the tissues in and about the wound is inevitable.

As a result of these injuries when the suture operation is completed the blood that has escaped on the free peritoneal surface and between the approximated infolded serous coats coagulates in a wedge shaped mass that plugs the line of suture throughout its entire extent (Fig. 2 A). There is also a certain amount of coagulated blood in the substance of the intestinal wall and about each suture hole. This coagulated blood is no doubt of importance in preventing leakage due to possible faulty operative technique. That it is not essential in preventing leakage if no technical errors are made would seem probable from the two anastomoses done on the intestine of a dead dog in which no coagulation of blood took place and yet which did not leak when subjected to extremely high pressures.

Depending on the amount of trauma done to the peritoneum and upon the quantity of blood extravasated more or less extensive

fibrinous adhesions occur. These develop very rapidly between the line of suture and the surrounding serous surfaces more particularly that of the omentum.

During the first hour following suture polymorphonuclear leucocytes make their appearance in the region of the wound. They may be seen in and about the engorged blood vessel invading the coagula and collecting about the buried sutures. Exudation of serum has begun by the end of the first hour. It is first noticeable between the muscle bundles of the muscularis.

Degenerative changes in those tissues which are fatally injured by the operative trauma no doubt start at once for it can be seen microscopically along the cut mucosal edges four hours after operation.

Reparative processes also no doubt begin very quickly. The intoldded cut edges of the intestinal wall make a ridge which juts into the lumen of the intestine (Fig. 2). The summit of this is composed of the exposed cut edge of the intestinal coats. Somewhere on the sloping sides of this ridge are the junctions between the living mucosa and the denuded area. This junction is often marked by a sulcus (Fig. 4 A). Within 24 hours fibroblasts can be observed proliferating just beneath the necrotic tissue and fibrin which cover the denuded area. Fibroblasts can also be seen beginning to invade the edges of the blood coagula in other parts of the specimen. In the sulcus at the edges of the ridge the epithelium lining the adjacent intact mucosa starts to proliferate growing in a flattened syncytial layer over the denuded surface. The appearance of this new forming epithelium closely resembles the embryonal form (Fig. 3 B). The cystic downgrowth of newly formed glands into the submucosa has begun by the end of 4 hours. This was described by Mall but he did not observe it until the sixth day.

During the next three days the congestion, the edema and the leucocytosis are on the increase. Grossly the fibrinous adhesions become progressively firmer and when torn away leave a reddened suture line with swollen edges. Inside the lumen the degenerated and dead tissue is separated from the

living and is cast off. The denuded surface of the ridge becomes smoothed over with a thin layer of fibrin beneath which granulations are springing up. From the sulci on either side the epithelium is growing over this smooth surface beneath the fibrin.

In seven to ten days the coagulum disappears and is replaced by new connective tissue. This contracts so that it is difficult to tell, microscopically exactly where the line of approximation is. The time required to cover the exposed surface of the inverted ridge is extremely variable. It depends largely on its surface measurements and elevation. Mall found it almost covered with a new mucosa after 15 days. In one of our cases it was not completely covered after 38 days. The average is about 21 days. The formation of new glands proceeds almost as rapidly as the growth of the new layer of the surface epithelium. The newly formed mucosa is at first thinner than normal and has no muscularis mucosae. After two months have passed however it is completely regenerated and cannot be distinguished from the surrounding undamaged mucosa.

After the seventh day the fibrinous adhesions between the suture line and the surrounding serous surfaces have for the most part, disappeared. Those that remain, become organized so that by the fourteenth day they are dense and fibrous and can only be torn away with great difficulty. As suggested by Prof. W. C. Clarke most of these also disappear gradually as the months pass. The movements that go on constantly within the abdominal cavity by gentle traction probably cause stretching of the connective tissue fibrillae; disappearance of the blood-vessels and gradual atrophy and disappearance of the adhesion band. It is common to find after one month only a single narrow band running from the cicatrix in the gut to the omentum or mesentery.

The realignment of the intestinal wall which is the fourth and final stage of repair according to Mall was not as complete in our cases as he seemed to find it. In none of the specimens examined by us did the infolded ridge disappear entirely. It undoubtedly grows much smaller. The circular muscle

appears to be realigned but we were always able to see connective tissue interrupting the course of the muscle-bundles. Marchand (10) said in this connection. The regeneration of the muscle bundles is not abundant enough to bridge small spaces of a few millimeters—if however muscle wound lies against muscle wound the scar macroscopically would conceal itself in the unbroken line of the fibers. That a certain amount of regeneration of smooth muscle can occur seems certain.

The epithelial lined cysts and tubes with adenomatous growths about them deep in the wall of the gut, which were first observed by Mall, we found in four of our cases ranging from 51 to 144 days after operation. They occur usually about a buried suture and have many polymorphonuclear leucocytes in and about them. Mall believed that they were implanted by the needle at the time of operation. They appear to be of purely pathological interest and to have no surgical significance.

Some remnants of the silk sutures were found in every case. In the older ones there were usually one or more loose ends lying free in the lumen covered with gritty material.

SUMMARY AND CONCLUSIONS

The following conclusions based on the data obtained from the operations on the normal and the gangrenous small intestine of the dog are grouped together for the reason that in both series the experiments were the same and the end results identical.

1. The non-infected suture line in the small intestine in dogs is very resistant to internal hydrostatic pressure. For at one hour after operation and any time thereafter the area of operation is capable of withstanding an hydrostatic pressure of over one pound per square inch without leakage.

2. The clinically infected specimens leaked at minimum pressures.

3. To obtain perfect results a proper technique is essential. For it is seen that in a dog recently killed the intestine when properly sutured, is capable of withstanding a pressure of nearly two pounds per square inch without leakage.

4 Imperfect technique results in a defective suture line. The defects if not too extensive may be sealed by the coagulum which probably prevents leakage.

5 The smooth muscle of the divided and sutured intestine retains its viability and segmenting function to within 5 mm of the line of suture.

6 In an infected case with gangrene around the suture line no segmentation occurred within 15 mm while 60 mm away contractions were powerful and well defined.

7 Repair in sutured intestinal wounds begins at once with the coagulation of the extravasated blood which fills in the space between the two approximated serous surfaces. This union becomes permanent in from 7 to 10 days with the replacement of the coagulum by connective tissue.

8 Repair of the mucosa is first seen after 24 hours beginning with a line of vital epithelial cells extending from the edge of the viable mucosa over the denuded surface of the intolled cut edges of the intestinal coat.

9 The denuded surface may be covered with an immature mucosa as early as the fifteenth day (Wall) but it is usually not completely covered until 23 days after operation.

10 Regeneration of the mucosa is complete after two months.

11 Complete anatomical regeneration of the muscularis does not occur. A realignment of the intolled muscular fibers occurs but it is always interrupted by a thin line of scar tissue.

From the above data we conclude that fluid and food may be given immediately after operation without danger of leakage in the sutured small intestine. If leakage does occur it is due to infection or faulty operative technique.

THE VALUE OF THE DETERMINATION OF THE CHOLESTEROL CONTENT OF THE BLOOD IN THE DIAGNOSIS OF CHOLELITHIASIS

By EDWIN HENES, JR., A.B., M.D., NEW YORK.

Assistant Adjoining Physician, German Hospital; Assistant Attending Physician, German Hospital Dispensary.

SINCE the publication in July 11, 1914¹ of a preliminary report on this subject my researches in cholesterinaemia have been continued in the laboratory of the German Hospital. My results seem of sufficient interest and importance to warrant a further more detailed report of my findings.

Much has been written in recent years on

the etiology and pathogenesis of gall stones. In the light of our newer researches the older theories became almost obsolete for they failed to take into consideration the fact that cholesterol is a substance which not only is constantly present in the circulating blood and all other body fluids (except urine under normal conditions) but that its amount varies considerably under different pathological conditions and under different clinical states.

¹ H. H. J. *The Value of the Determination of the Cholesterol Content of the Blood in the Diagnosis of Cholelithiasis*. *J. Am. Med. Assoc.*, 1914, 6.

The formation of a calculus, whether that take place in the genito-urinary, intestinal or biliary tract, is absolutely a physical process undoubtedly dependent upon an altered chemical state of the medium in which the calculus forms. Over fifty years ago Thudicum originated the theory that gall stones were formed by the precipitation of cholesterol and certain calcium compounds as a result of the bile becoming acid. Since the discovery of bacteria, we ascribe chemical changes to bacterial growth and activity. Infection and inflammation of the gall-bladder certainly play a rôle in the formation of gall stones. Bacterial growth in bile alters the chemical composition of the bile. Inflammation of the gall bladder mucosa results in epithelial desquamation and the formation of nuclei for gall stones. But surely the male gall-bladder is just as susceptible to infection as is the female gall bladder and statistics show that 75 per cent of cases of gall stones are found occurring in females. Gall stones are not dependent for their formation upon a primary infection of the gall bladder for we see many cases of cholelithiasis in which the removed gall-bladders show no evidence of the slightest amount of inflammation. It is just as logical to conclude that the stones are the primary cause of the inflammation.

The most recent, and probably the most generally accepted classification of gall stones is that of Aschoff and Baemelster.¹ They classify them as follows:

1. Pure cholesterol stones.
2. Stratified cholesterol-calcium stones.
3. Cholesterol-pigment — calcium stones, which are most frequently found.
4. Composite stones made up of cholesterol and a mantle of cholesterol and calcium.
5. Bilirubin-calcium stones, which are seldom found in the gall bladder but usually in the bile passages of the liver itself.
6. Calcium-carbonate stones which are very seldom found.

The amount of calcium and bile pigments found in gall-stones is very trifling. From an analysis of many stones — an analysis

which sought merely to determine the amount of cholesterol in relation to the whole stone — it can be safely said that cholesterol composes at least 95 per cent of all stones in which cholesterol is a part of their composition.

All authorities in considering the etiology and incidence of gall stones agree upon the following facts:

1. Most of the cases are found occurring in females.

2. A very close relationship between pregnancy and gall stones. Osler in his *Principles and Practice of Medicine* states that 90 per cent of women who have gall stones have borne children and Mayo states that 90 per cent of women who have gall-stones and have borne children identify the beginning of the symptoms of cholelithiasis with some particular pregnancy. The relation of gall stones to pregnancy was formerly ascribed to the excessive metabolic burdens assumed by the liver during the course of pregnancy burdens which the liver failed to carry on. It seems very unreasonable to believe that the body in general and the liver in particular would fail to assume the extra burdens imposed by so normal and physiologic a process as pregnancy.

3. A relationship between typhoid fever and cholelithiasis. It is needless at this time to elaborate on this subject. Cases of gall stones following typhoid fever and cases of gall stones in those who have had typhoid fever are far too numerous to allow of the assumption of a mere coincident relationship.

The past few years have largely increased our knowledge of cholesterol. The presence of a rather definite amount of cholesterol in the blood under normal conditions has been definitely established. The study of cholesterinaemia under pathological conditions has proved the existence of a hyper and a hypocholesterinaemia, and our researches have been sufficiently extensive to permit us to conclude in what diseases, and under what clinical states, we can expect a hyper or a hypocholesterinaemia.

One of the characteristics of pregnancy is a progressive increase in the amount of chole-

terol in the blood. At term a definite hypercholesterinaemia is found and it persists for some time after the birth of the child.

In typhoid fever as soon as a convalescence sets in we note a decided rise above the normal in the cholesterol content of the blood. This hypercholesterinaemia also persists for some time. We have therefore a hypercholesterinaemia in the two most important etiological factors in the genesis of gall stones, in the genesis of calculi which are largely if not entirely composed of cholesterol.

In interpreting the cholesterinaemia in an individual case it is of first importance to know the clinical states and diseases which are accompanied by a rise or fall of the cholesterol in the blood. Pregnancy and typhoid fever have already been referred to.

The influence of fever is marked and always reduces the amount of cholesterol found in the blood. The higher the fever the more marked this influence is.

Progressive arteriosclerosis is accompanied by a moderate hypercholesterinaemia. It is during the stage of the disease before the vessel walls become calcified that this hypercholesterinaemia is noticed. In the old arteriosclerotics in the type who go on to apoplexies the increase in the cholesterol of the blood is not so marked. In fact our researches show that there is actually a reduction probably due to the deposit of cholesterol in the vessel wall.

In chronic nephritis a hypercholesterinaemia is found except when the disease has gone on to uraemia when there is a decided fall. For details I refer the reader to a recent paper¹ on the subject.

Jaundice is always accompanied by an increase of cholesterol in the blood. This is especially true in all cases of obstructive jaundice.

Additional researches in cases of obesity and diabetes will probably show an accompanying hypercholesterinaemia in these conditions.

The normal cholesterinaemia has been placed between 0.0010 and 0.00180 grams per 1 ccm. serum.

¹ Henes J. *Ueber die Abweichungen des Cholesteringehalts des menschlichen Blutes bei verschiedenen Krankheiten.* N. Y. St. J. Med. v. 3, August.

Before proceeding with the presentation of cases I wish to assert very emphatically that despite all that has been said and written for and against this and that method for the quantitative determination of cholesterol in the blood I continue to find the method outlined in detail in one of my first papers² the best and most serviceable.

The following cases are presented to show that a hypercholesterinaemia accompanies cholelithiasis and that a quantitative determination of the cholesterol of the blood when properly interpreted can be and is of great diagnostic importance and value. The cases are presented as briefly as possible and all irrelevant data has been omitted.

CASE 1. Male age 38 years admitted to the hospital with the diagnosis of cholelithiasis. No fever no jaundice no sclerosis. Besides the rather typical symptoms of gall stones the patient showed signs and symptoms strongly suggestive of duodenal ulcer. The stomach analysis was negative. Here was a case in which it was very difficult to make a definite pre-operative diagnosis, and on in whom nothing was found that could influence the cholesterinaemia. The examination of the blood showed the serum to contain 0.00106 gr. of cholesterol to 1 ccm. of serum — an amount far in excess of the normal. Operation revealed the interesting condition of a duodenal ulcer and an inflamed gall bladder with stones.

CASE 2. Male age 58. Temperature 101 F. slight icterus moderate sclerosis no evidence of nephritis. Patient has had attacks of colic and jaundice at intervals. On admission to the hospital the symptoms were referable to the gall bladder. Wassermann reaction negative. Here we have a case in whom there exists clinical conditions which conflict as far as their influence on cholesterinaemia is concerned. The fever tends to reduce while the slight jaundice and sclerosis tend to increase the cholesterol content of the blood. Blood examination showed 0.00187 gr. cholesterol per 1 ccm. serum an amount difficult to interpret under the circumstances. Operation revealed a cholecystitis with gall stones.

The influence of fever on the cholesterol content of the blood is a very definite one and always reduces it. One must constantly bear this in mind in determining the cholesterinaemia in the making of a diagnosis. The following two cases clearly show the influence of fever.

² Ueber die Bestimmung des Cholesteringehalts des menschlichen Blutes bei verschiedenen Krankheiten. Deutsch. Arch. f. klin. Med. 19, 3, 104.

CASE 3. Female, 47 years. Urine negative for nephritis, no jaundice, no scleroses. Temperature of F in past four days had slowly come down from 3 F. White blood-cells, 3,000 polymorphs, 84 per cent. Symptoms referable to gall-bladder and a diagnosis of empyema of gall was made. Blood showed 0.0031 gr cholesterol per 1 ccm. serum, a practically normal amount. Operation revealed an empyema of the gall-bladder and gall-stones. Eight days after the cholecystectomy, during which time 900 ccm. bile had been drained (entailing an absolute loss of cholesterol to the body), with the temperature at 100 F the blood showed 0.00247 gr of cholesterol per 1 ccm. serum.

CASE 4. Female, age 41 years. Urine negative, no scleroses, no jaundice. Two weeks after a ventral suspension for uterine prolapse, the patient began to complain of severe epigastric pain, and showed signs and symptoms referable to the gall-bladder. Temperature 102.6° F. White blood-cells, 22,400 polymorphs, 85 per cent. Diagnosis acute cholecystitis. Patient gave no history of typhoid fever nor did she give any evidence of having it at the time. The blood showed 0.008 gr cholesterol per 1 ccm. serum. Operation showed an acute suppurative cholecystitis with gall-stones. A few days later a positive Widal reaction was obtained and a culture taken from the gall-bladder at the time of operation showed bacillus typhosus. A week after the cholecystectomy with the temperature 100 F the blood showed 0.00353 gr cholesterol per 1 ccm. serum.

CASE 5. Female, age 36 years, admitted to the hospital with a diagnosis of acute appendicitis. Temperature 100° F. Urine showed heavy trace of albumin, and much pus occasioned by a purulent vaginal discharge. Subsequent urine showed no evidence of nephritis. No jaundice, no scleroses. The acute abdominal symptoms were referable to the right hypochondrium and kidney region, and while under observation, symptoms suggested those of duodenal ulcer and gall-stones. The blood showed 0.00143 gr of cholesterol per 1 ccm. serum, an amount just about normal. Ten days after admission the patient was operated upon and a definite pre-operative diagnosis of cholelithiasis was made. Operation revealed an absolutely normal stomach, duodenum, and gall-bladder and a diseased appendix, which was removed. Here in my opinion, we had, or rather the surgeons had, an opportunity to make a definite and correct pre-operative diagnosis, in a case which was rather puzzling.

The following case was especially interesting to me for it chanced to put my ideas on the subject of cholesterinaemia and cholelithiasis to a severe test.

CASE 6. The patient a physician, about 36 years old, was referred to me by a colleague, an eminent surgeon in New York. At the time the blood was taken for examination the patient had no

fever, urine was negative for nephritis, vessels showed no scleroses, and he was very slightly jaundiced. The blood and urine did show a trace of bile. Clinically we were dealing with a case of cholelithiasis, with a history of four years. Four days later the patient developed pronounced jaundice which came on rapidly and the X-ray report, thickened gall bladder with shadow suspicious of gall-stones greatly strengthened the surgeon's faith in his diagnosis. The examination of the blood showed 0.09 gr cholesterol per ccm serum. Under the circumstances, amount certainly not in favor of gall-stones. About month later the patient was brought to the hospital, his jaundice had markedly diminished (and he gave no history of having passed a stone) and an operation performed. The gall bladder as perfectly normal, and a small lymph node removed showed inflammatory changes. We all came to the conclusion that we had been dealing with a case of catarrhal jaundice. A proper interpretation and recognition of the value of the cholesterol determination would have availed an operation in this case.

In presenting these cases I have selected from a series of more than 100 cases those which show not only that a hypercholesterinaemia accompanies gall-stones but that a correct pre-operative diagnosis can be made in those difficult right-sided abdominal conditions which so frequently simulate one or the other of the following conditions: appendicitis, cholelithiasis, duodenal ulcer and peritoneal adhesions. My series of cases show that a cholesterol determination and a proper interpretation of the amount found is almost invariably of distinct value not only in diagnosis, but in the therapeutic indication.

CASE 7. Male, 40 years. Temperature 99.8° F. Urine negative, no scleroses, no jaundice, symptoms referable to stomach, gall-bladder, right kidney and appendix, case in which cholesterol determination could be of value. Blood showed 0.001 gr cholesterol per ccm. serum and under the circumstances a diagnosis of chronic appendicitis was made. Operation revealed normal gall-bladder, stomach, and duodenum, and a chronically inflamed appendix.

CASE 8. Male, age 35 years. Temperature 100° F. Urine showed no evidence of nephritis, no scleroses, no jaundice. Stomach analysis negative. Symptoms were definitely related to the gall-bladder sufficiently characteristic to warrant a pre-operative diagnosis of cholelithiasis. Cholesterol determination showed 0.016 gr per 1 ccm serum, an amount opposed to the diagnosis made. Operation revealed a normal gall-bladder with thick, but no stones, and a chronically inflamed appendix.

In justice to my contention and in furtherance of the interest of the cases presented I wish to add that the pathological diagnoses in individual cases have been taken from the report of the Pathological Laboratory.

CASE 9. Male age 25 years. Nephritis no fever no jaundice no sclerosis. Symptoms referable to the gall bladder and duodenal ulcer. One of gall tones or duodenal ulcer. The X-ray report was one of duodenal ulcer. The blood examination showed 0.00163 gr of cholesterol per 1 ccm serum, an amount not in favor of gall stones. Operation revealed a perforated duodenal ulcer.

CASE 10. The following case is one in which I have no operation to present. It is never theless an instructive one. Male age 1 years. Temperature 101.4 F. Urine negative. Light sclerosis. White blood cells 12,000 polymorphonuclears 94 per cent. No jaundice no admission at which time a diagnosis of appendicitis with reservation was made. The symptom were all referable to the upper abdomen but without definite local signs other than tenderness over the gall bladder. Blood examination at this time showed 0.00234 gr cholesterol per 1 ccm serum, an amount which in the presence of 101.4 F is decidedly above normal and under the circumstances strongly in favor of gall stones. The day after admission without any new symptoms jaundice developed. A few days later the temperature reached normal the jaundice had disappeared and all symptoms had vanished with the result that the patient insisted on being discharged from the hospital. In my opinion we were without doubt dealing here with a case of cholelithiasis.

CASE 11. Here is another case which did not come to operation. I present it because of the decided hypercholesterinemia found. Male age 40 years. No fever no nephritis no jaundice no sclerosis. Symptoms were referable to the right hypochondrium and were strongly suggestive of ulcer of the stomach or duodenum. The blood serum showed 0.00304 gr cholesterol per 1 ccm. The patient left the hospital refusing operation. This is just the type of case in which the cholesterinemia has been most helpful. A case in which the symptoms suggest either an ulcer or gall-stones, and in which the cholesterinemia is decidedly above normal (no other clinical cause being found that could account for the hypercholesterinemia). Such a case is usually one of cholelithiasis, and my experience forces me to maintain that opinion despite roentgen ray findings.

CASE 12. Female age 46 years. Temperature 101.4 F. White blood-cells 12,000 polymorphonuclears 81 per cent. No jaundice no sclerosis no nephritis stomach analysis negative. Symptoms referable to stomach and gall bladder. The blood showed 0.00392 gr cholesterol per 1 ccm serum. This case also refused operation, but a

diagnosis of cholelithiasis is the only one to make under the circumstances even if the temperature had been normal.

The following case is recorded to show a type in which it is very difficult to properly interpret the cholesterinemia.

CASE 13. Female age 68 years. No fever. Urine showed albumin hyaline and granular casts. No jaundice moderate sclerosis. Symptoms referable to stomach and gall bladder. Gastric analysis negative. The blood serum showed 0.0063 gr cholesterol per 1 ccm. We have here an adult female with the sclerosis one would expect and evidences of a nephritis to conditions which in themselves are accompanied by a hypercholesterinemia. One cannot depend upon the cholesterinemia for a definite diagnosis in case of this sort. Although the case refused operation the X-ray showed a large distinct stone in relation to the duodenum. In the straightforward undoubted cases of cholelithiasis we are perhaps not in need of further aids in diagnosis. In my experience I have not seen a case of gall tones verified by operation without an appreciable hypercholesterinemia.

CASE 14. Female age 43. Temperature 100 F. Urine negative no jaundice no sclerosis. Clinically a case of cholelithiasis. Serum cholesterol 0.00303 gr per 1 ccm. Operation chronic ulcerative cholecystitis with gall stones.

CASE 15. Male age 42 years. No fever no jaundice no sclerosis no nephritis. Diagnosis cholelithiasis. Serum cholesterol showed 0.00380 gr per 1 ccm. Operation chronic catarrhal cholecystitis with gall stones.

CASE 16. Female age 3 years. Temperature 101.4 F. No sclerosis no nephritis no jaundice (Had been jaundiced two months ago). Stomach analysis negative. Diagnosis cholelithiasis. Serum cholesterol 0.00120 gr per 1 ccm. Operation cholecystitis with gall stones.

CASE 17. Female age 40 years. No fever no jaundice no sclerosis no nephritis. Stomach analysis negative large tender tumor mass in relation to lower border of liver. Diagnosis cholelithiasis. Serum cholesterol 0.00120 gr per 1 ccm. Operation Chronic suppurative cholecystitis with gall stones.

My researches along these lines have convinced me that a cholesterol determination when properly interpreted is of real value in the diagnosis of those obscure conditions whose symptoms focus attention to the right side of the abdomen. Modern X-ray technique has materially helped us in clearing up these same difficult cases and especially does that apply to lesions within the stomach and duodenum. Roentgenologists must admit

that they have, as yet, failed to reach a sense of security in the X-ray diagnosis of gall-stones. In the following cases in which I mention the X-ray findings, I do so merely to emphasize the importance and value of serum cholesterol determinations.

CASE 18. Female, age 50 years. No fever no nephritis, no jaundice never pregnant, never had typhoid fever. Symptoms are abdominal pains closely simulating those of gall-stones. White blood-cells, 9400 polymorphonuclears, 68 per cent. Stomach analysis negative except for low acidity, no sclerosis had never been jaundiced. X-ray report: Shadows suggestive of gall-stones. The serum-cholesterol equaled 0.00209 gr per 1 ccm., an amount not sufficiently high to be in favor of gall-stones. After observing the case for several days a diagnosis of gall-stones was made. Operation revealed a perfectly normal gall-bladder without stones, and some adhesions about liver and spleen.

CASE 19. Male, age 46 years. Temperature 99 to 100 F (the day previous had been 100 F). Moderate jaundice, urine negative. Symptoms referable to right upper quadrant of abdomen, and the case impressed us as a case of gall-stones. Serum cholesterol showed 0.00317 gr per 1 ccm. and the X-ray department reported "Mottled shadows suspicious of gall-stones. Operation revealed gall-stones."

CASE 20. Female, age 46 years. No fever no jaundice, no sclerosis, no nephritis. Symptoms definitely relative to the gall-bladder and she gave a history of repeated attacks of pain and jaundice. The blood examination showed 0.00300 gr cholesterol per 1 ccm. serum and the report from the X-ray department was in substance, no gall-stones. Operation showed a chronic ulcerative cholecystitis with one large pure cholesterol stone, a type of stone which does not show up well on the X-ray plate.

CASE 21. Female, age 26 years. Temperature 100 F. No jaundice, no nephritis, no sclerosis slightly obese. Symptoms were referable to the gall-bladder. The blood showed 0.0031 gr cholesterol per 1 ccm. serum, and the X-ray report read "No evidence of gall-stones. Operation revealed an inflamed gall-bladder containing six large cholesterol stones."

CASE 22. Male, age 28 years. No fever no jaundice, no nephritis, no sclerosis. Never had typhoid fever. For the past two years he has had symptoms suggesting duodenal ulcer or gall-stones for a long time had duodenal feeding seven months ago appendectomy without any relief Vomiting has always been the chief symptom. The blood showed 0.00107 gr cholesterol per 1 ccm. serum, and the X-ray department reported shadows suggesting gall-stones. A diagnosis of cholelithiasis was made. The findings at operation were practically negative, except for adhesions between the gall

bladder liver and duodenum gall-stones or ulcer were not to be found.

CASE 23. Female, age 45 years. No fever no jaundice, no nephritis. Symptoms referable to stomach. Despite negative stomach analysis, we were, apparently dealing with a case of gastric ulcer that, at least, was the clinical picture presented. The blood showed 0.0084 gr of cholesterol per 1 ccm. serum, and the X-ray department reported one large gall-stone. A second X-ray picture also showed three large stones. Operation revealed a catarrhal cholecystitis with gall-stones. The gall-bladder contained three large stones and many very small ones. There was no evidence of an ulcer of the stomach.

It will be noted from these latter cases, that the cholesterol determination correctly foretold the condition eventually found at operation a claim which I cannot make for the X-ray.

CASE 24. Female, age 48 years, was admitted to the hospital complaining of pains and swelling of lower extremities and pain in lumbar regions. No fever nephritis, no jaundice (had been jaundiced two years ago) no sclerosis. Wassermann reaction negative white blood-cells 8500 polymorphonuclears, 71 per cent. hemoglobin, 70 per cent. Stomach analysis showed 3.4 free hydrochloric acid, 64 total acid, no lactic acid, and no blood. The physical examination showed the lower border of the liver reaching to a line connecting the anterior superior spine of ilium with the umbilicus. Its surface was smooth. Below the edge in the gall-bladder region was a rounded nodular hard mass, the size of a walnut which can be separated from the liver and is tender. Underneath the liver and more posteriorly in lumbar region, a similar mass can be felt. Virchow glands felt. I present this case in more detail because of its interest. The patient's general appearance suggested malignant disease. A neurological examination further suggested the probability of spinal cord metastases. The X-ray examinations of the spinal column and abdomen were negative. A cholesterol determination showed 0.00356 gr per 1 ccm. serum. Despite this hypercholesterolemia, a diagnosis of carcinoma of liver or colon was made, and an exploratory operation performed. The surgeons were very much surprised to find gall-bladder full of stones. It was the gall-bladder that was the mass originally felt. No evidence of malignant disease was found. Subsequent neurological examination of the patient resulted in the conclusion that the symptoms at first thought to be due to malignant cord metastases were due to a multiple sclerosis.

CASE 25. Female, age 29 years. Married last child 8 months ago. Symptoms referable to gall-bladder began 2 months ago. Never jaundiced and not now. Temperature 100° F. White blood-cells 7800 polymorphonuclears 7 per cent. Neph-

ritis, no sclerosis. Clinically a case of cholelithiasis. Cholesterinaemia 0.0025 gr per 1 ccm serum. Operation revealed a few small stones in the cystic duct.

CASE 26 Female age 35 years. Temperature 98.8° to 100.2° F. No nephritis, no jaundice, no sclerosis. Four pregnancies last one eight months ago. Symptoms referable to right upper and lower quadrants. Stomach analysis negative. Cholesterinaemia 0.0021 gr per 1 ccm serum. Operation revealed a gall bladder containing a few small stones and a bronchially inflamed appendix.

CASE 27 Female age 66 years. Ten pregnancies last 16 years ago. No jaundice. Temperature had been 102° F the day before the blood was examined. Urine showed a trace of albumin, a few granular casts, and the arteries showed moderate sclerosis. The blood pressure was 161 mm. White blood-cells 5,400 polymorphonuclears 86 per cent. Symptoms referable to the right lumbar region. Stomach analysis showed no free hydrochloric acid and a diminished total acidity. Clinically we were dealing with a case of gall stones. With a coincident evidence of nephritis and some sclerosis, a moderate hypercholesterinaemia was to be expected. The blood showed 0.00334 gr cholesterol per 1 ccm an amount which in the presence of the 102° fever the day before must be looked upon as a decided increase above the normal. In this case I have no post-operative findings. The patient left the hospital refusing operation.

In three private cases which came under my observation in whom there was absolutely no doubt as to the diagnosis of gall stones, and in whom there were no coincident conditions that would influence the cholesterinaemia I obtained figures of 0.00200, 0.00320 and 0.00347 gr cholesterol per 1 ccm serum. None of these cases has as yet come to operation.

My series of cases includes many which at operation showed either ulcer of stomach, ulcer of duodenum, intestinal adhesions, chronic appendicitis or carcinoma of pylorus conditions which very frequently are to be differentiated from cholelithiasis. Because I do not consider the facts of interest I shall not present those cases whose cholesterinaemias verified the operative findings when those findings were other than gall stones.

Through the courtesy of Dr. Allen O. Whipple I was permitted to examine the blood of several cases referred by him from the services of Drs. Brewer, Elliot and Longcope of the Presbyterian Hospital.

CASE 28 Female age 37 years. Sixteen pregnancies, no jaundice, no sclerosis, no nephritis. Temperature 101° F. White blood-cells 12,500 polymorphonuclears 80 per cent. Symptoms and physical signs all referable to the gall bladder. Serum-cholesterol amounted to 0.00430 grs. per 1 ccm and would have been even higher with normal temperature. Diagnosis of cholecystitis with gall stones was made and operation verified it. About 18 calcium bilirubin cholesterol stones were found in the gall bladder.

CASE 29 Female age 35 years. Typhoid fever 2 years ago. Present history dates back seven years and began while she was four months pregnant. Has had four attacks in seven years of epigastric pain, nausea, vomiting and jaundice. At present no fever, no nephritis, no sclerosis, but very slight icterus. Serum-cholesterol showed 0.0022 gr per 1 ccm serum. The diagnosis of cholelithiasis was verified at operation and fifteen small mulberry-like cholesterol calcium bilirubin stones found.

CASE 30 Female age 54 years. Pain in epigastrium, nausea, vomiting, chills, fever and jaundice coming on in attacks. First attack sixteen years ago after her first pregnancy. Has been pregnant four times since then. At the time the blood was examined the patient was slightly jaundiced, had no fever, no sclerosis. White blood cells 27,300 polymorphonuclears 90 per cent. Wassermann negative. Urine showed very faint trace of albumin and 2.5 per cent sugar. The blood sugar equals 0.146 per cent. Cholesterinaemia in this case amounted to 0.00276 gr per 1 ccm serum. This patient was not operated on, but during her stay in the hospital several faceted gall stones were passed in the feces.

In reviewing the last case the question immediately arises why was not the amount of cholesterol in the blood even higher for the jaundice and the diabetes are in themselves accompanied by a hypercholesterinaemia. In attempting to answer that question the whole subject of the local deposit of cholesterol must be considered. Gall stones are not the only local deposits of cholesterol. In arterio-sclerosis and atheroma of the aorta it has been repeatedly demonstrated that cholesterol is deposited in the walls of the blood vessel. The yellowish plaques found in the atheromatous aorta are largely composed of cholesterol and these plaques are not the result of an infiltration but rather a deposit. The older the process the greater the deposition and eventually the vessels become impregnated with lime salts. It is only in this stage of arteriosclerosis that we

see our apoplexies. And it is during this stage that the cholesterinaemia is not as marked as during the progressive stage. Can we not conclude that the blood-cholesterol is decreased somewhat, because it is slowly becoming deposited elsewhere?

The chronic nephritics who go on to so-called albuminuric retinitis also show the effect on the amount of cholesterol in the blood of the deposition, or in this case infiltration of the retinal tissue with cholesterol. It has been shown that the retinal plaques are composed largely of cholesterol and it has further been shown that cases of nephritis with retinitis, have less cholesterol in the blood than cases of nephritis without retinitis. Can we not again conclude that this diminution is the result of local deposition or infiltration? This same theory I am applying in cases of cholelithiasis. The constant deposition of cholesterol in the gall bladder in the formation of gall stones must slowly deprive the blood of some of its cholesterol. Perhaps this would explain some of the comparatively low figures we get despite the presence of gall stones. This then would bring up another point in the proper interpretation of the cholesterinaemia in individual cases. In the last case presented the patient gave a history of sixteen years. Had we examined her blood ten years ago the amount of cholesterol in the blood might have been considerably higher than 0.00376 gr per 1 cc. A careful history to determine the onset of the gall bladder trouble is, in my opinion an important element in the interpretation of the cholesterinaemia.

CASE 3 (from the Presbyterian Hospital) Female, age 50 years. Has had five attacks of severe, colicky epigastric pain, radiating to the back, with vomiting and jaundice. Has never had typhoid fever and has been pregnant nine times. No sclerosis, no fever, no nephritis, very slight icterus. Serum cholesterol amounted to only 0.0077 gr per 1 cc. and yet at operation, the gall-bladder was found full of small stones. In this case we did not obtain a careful history.

CASE 32 Male, age 63 years. Temperature 100° F. Moderate sclerosis, slight jaundice. Urine showed heavy trace of albumin, but no casts. Symptoms and physical signs were all referable to the gall-bladder. Here again, the comparatively low figure of 0.0024 gr of cholesterol per 1 cc.

serum was found and the operation revealed gall stones. In this case, also we have no accurate history of the duration of the trouble. In my opinion, we must, in the future, ask ourselves: If this patient has gall-stones, how long has he had them?

CASE 33 (from Presbyterian Hospital) Female, age 43 years. Had been on the Medical Service for two months with pyrexia when present attack began. Pain and tenderness in right upper abdominal quadrant with vomiting. Tender mass in the region of the gall-bladder. No jaundice, no sclerosis, no nephritis. Temperature 100° F. White blood cells, 10,000 polymorphonuclears, 78 per cent. Widal negative. Wassermann negative. Has never had typhoid fever and has not been pregnant. The blood showed 0.0001 gr of cholesterol per cc. serum, an amount which must be looked upon as high in the presence of 100° F fever. Operation revealed 65 gall-stones, with recently formed layers of cholesterol.

CASE 34 (from Presbyterian Hospital) Female, age 36 years. Onset of trouble six years ago while pregnant the twelfth time. Never had typhoid fever. Temperature 100° F. White blood cells, 8,000 polymorphonuclears, 86 per cent. Wassermann negative. No jaundice, no sclerosis, no nephritis. Pains in right upper abdominal quadrant simulating gall stone colic. Serum-cholesterol amounted to 0.0033 gr per 1 cc. serum, an amount in favor of cholelithiasis under the circumstances. On operation, a markedly thickened gall bladder containing several ounces of pus and 30 gall-stones were found.

CASE 35 (from Presbyterian Hospital) Female, age 35 years. Three pregnancies, never had typhoid fever. Temperature 100.4° F. No nephritis, no sclerosis, slight icterus. White blood cells 9,400 polymorphonuclears, 4 per cent. Wassermann negative. Symptoms strongly suggestive of gall stone colic. The blood showed 0.0007 gr cholesterol per 1 cc. serum. At operation, the gall bladder was found large and thick, containing 6 ounces of thick viscid bile and three gall-stones.

CASE 36 (from Presbyterian Hospital) Female, age 38 years. For past six months epigastric pain, vomiting, and for past few days slight icterus. Has been twice pregnant. No sclerosis, no fever, no nephritis. Definite tenderness in right upper abdominal quadrant where a mass can be felt. Blood showed 0.00356 grams of cholesterol per 1 cc. serum. Operation showed the cystic and common ducts distended with soft mushy material and many small stones.

CASE 37 (from Presbyterian Hospital) Female, age 43 years. History of epigastric pain radiating to back and right scapular region, fever, vomiting. In past five years has had several such attacks. Has never had typhoid fever, has never been pregnant. At present, no jaundice, no fever, no nephritis, no sclerosis. Exquisite tenderness over the gall-bladder and a mass is felt. Cholesterinaemia amounted to 0.0038 gr per 1 cc.

serum. Operation revealed a distended gall bladder and a pure cholesterol stone impacted in the cystic duct.

CASE 38 (from Presbyterian Hospital). Female age 50 years. History of pain in right upper quadrant onset sudden six months ago with pain in region of gall bladder. Has had four attacks and intermittent jaundice. Typhoid fever at 14 years. Seven pregnancies. At present no sclerosis no fever no nephritis but jaundice. Cholesterinaemia amounted to 0.0031 gr per 1 cc serum. At operation a very interesting condition was found. No gall bladder was to be found the only suggestion of it was a small narrow strip of tissue where the gall bladder should be. The common duct was dilated to the size of a finger. In the lower part of the duct a single oval gall stone was found. It had a cholesterol nucleus and a cul ure from the center of the stone showed bacillus protea.

These 38 cases presented are sufficient to show that in the great majority of cases a hypercholesterinaemia accompanies cholelithiasis. It is needless to enumerate more instances. They also show that the cholesterinaemia must be studied in relation to the clinical condition of the patient at the time the blood is examined before it can be properly interpreted and made to assist in deriving a correct diagnosis. We must make the necessary allowances for the presence or absence of fever jaundice nephritis progressive arteriosclerosis and must also take into account the duration of the process of deposition in the gall bladder. These cases further show that a classical picture of gall stones can prove to be a duodenal ulcer and a classical picture of duodenal ulcer can prove to be gall stones. It is in just such cases that dependence upon a cholesterol determination when properly interpreted will be of great help in making a correct diagnosis and at times cholesterinaemia has almost shamed the X ray.

A hypercholesterinaemia in the absence of arteriosclerosis jaundice and nephritis does not necessarily mean the presence of gall stones. In my opinion we must realize that we are dealing with what can be likened to a diathesis, a cholesterol diathesis. This diathesis is either distinctly pathological in that it may result in arteriosclerosis local or general or in gall stones or it manifests itself as a protective agency as in the infec-

tious diseases and nephritis. Only a careful metabolic study can clear up the many doubtful aspects of the subject of cholesterinaemia.

The following are cases in which the cholesterinaemia was not indicative of the operative findings.

CASE 39 (from Presbyterian Hospital). Female age 31 year. No fever no jaundice no sclerosis no nephritis. No typhoid fever and has been pregnant six times. Signs and symptoms referable to the appendix. Blood showed 0.0027 gr cholesterol per 1 cc serum but at operation a perfectly normal gall bladder was found. Diagnosis appendicitis.

CASE 40. Male age 53 year. No fever no jaundice no nephritis moderate sclerosis. At first symptoms were referable to the right kidney subsequently attention was attracted to the gall bladder. Cholesterinaemia amounted to 0.00330 gr per 1 cc serum a figure that under the circumstances is suggestive of gall stones. Operation revealed a perfectly normal gall bladder stomach and duodenum. I have no further post-operative record. As for the arteriosclerosis in this case I am not willing to state that it alone was responsible for the hypercholesterinaemia.

CASE 41. Female age 64 years giving symptoms of gall stones. No fever no jaundice no nephritis. Gastro-intestinal tract negative by X ray examination. This patient had marked arteriosclerosis. Cholesterinaemia amounted to 0.00310 gr per 1 cc serum an amount which the sclerosis in this case could account for. The operation revealed intestinal adhesions and a normal gall bladder.

These three cases are the only ones in a series of 128 (including the cases presented in the preliminary report on the subject) in which the cholesterol estimation of the blood did not foretell the actual condition eventually found at operation or the definite diagnosis made on the discharge of the patient from the hospital. And in no case of cholelithiasis verified by operation did the blood fail to show a hypercholesterinaemia. Naturally those cases which showed coincident conditions which influenced the cholesterinaemia are not included in that statement.

We cannot overlook the interest and especially the importance of these facts. They prove that a properly interpreted cholesterol determination is of great help not only in the diagnosis of cholelithiasis but also in the differential diagnosis of those diseases which so often simulate cholelithiasis.

DEPARTMENT OF TECHNIQUE

SURGICAL REPLACEMENT OF THE PROLAPSED KIDNEY¹

B. DOUGAL BISSELL, M.D. F.A.C.S. New York

Attending Surgeon Woman's Hospital

SINCE Hahn's initial effort to save the prolapsed kidney and restore it to its normal place and efficiency there have been devised many surgical procedures with the same conservative object in view. But the evolution of nephropexy from 1881 has been slow and varied. The original plan namely splitting the fatty capsule down to the outer portion of the kidney stitching this capsule to the wound and packing the wound with carbolized gauze, has been variously modified by those who followed Hahn, but all efforts to permanently fix the kidney were equally unsatisfactory.

Senn in 1897 appreciating the failure of preceding methods, instituted a radical change, namely the suspension of the organ by means of a strip of gauze passed around the lower pole. In this way he hoped not only to make fixation more certain but to restore the kidney to its normal position. Deaver and Da Costa modified Senn's method by passing a sling around each pole. Fisher employed two decalcified bone drains and Beyer two rubber drains in the same manner. Chambers in 1901 passed a catgut suture around the lower pole. In some of these procedures the fatty capsule was removed but in none of them was the fibrous capsule utilized directly or indirectly as an extra means of support.

Another important improvement in the technique of fixation was made by Lloyd who reflected the fibrous capsule of the convex border of the kidney so that the denuded surface might be apposed to the abdominal wall for fixation. To maintain the kidney in position until union took place Lloyd and some who followed him passed sutures through the kidney substance and both attached and reflected layers of the fibrous capsule. Others utilized the fibrous layers for support by stitching them in the wound.

Previous to October 15, 1907 I employed the technique then in common use namely exposing the convex border of the kidney and maintaining the organ in position by means of the sutures

passed through the reflected fibrous layers and through tissues in the region of the wound. My results were most discouraging and I became convinced that one of the chief faults in this technique was the failure to maintain the kidney in position long enough for firm union to take place. I reasoned that as the fibrous capsule varied greatly in thickness and strength, it was not dependable and constituted an element of weakness in technique so that when force from above was directed against the kidney after operation such as results from vomiting and deep breathing the sutures might tear through the fibrous layer to which they were attached, and that if we could adopt some method by which the dependence upon this capsule for support could be eliminated the problem of fixation would approach solution. This reasoning led me to pass about each pole sustaining sutures of chromic catgut. Results of this technique showed me there were a sufficient number of unsatisfactory cases to convince me that the technique failed to meet all conditions. These results proved to me that the convex or outer border was too limited a surface for fixation and that even though the kidney became attached its position was not always relatively normal and lateral motion was permitted. As the result of such reasoning I adopted a radical change in preparing the kidney for fixation. I.e. exposing the greater part of the posterior surface and using the fibrous capsule to prevent the fat from wedging its way between the apposing surfaces.

Such is a brief résumé of the important steps in the evolution of the method herein advocated.

In discussing the surgical problem of permanent replacement of the prolapsed kidney the approach to the organ demands our first consideration. The posterior or lumbar route is now generally selected but the technique of approach varies and has not yet been standardized. In the technique of approach which I prefer the initial incision begins over the twelfth rib about five centimeters from the spine a little above and to

¹Read before the Medical Society of the County of New York April 26, 1914.

the inner side of the angle formed by the last rib and the erector spina and extends downward and outward ten or more centimeters to a point near the crest of the ilium immediately above Petit's triangle. The tissues covering the erector spinae and the latissimus dorsi are dissected from these muscles so as to completely expose them to view. The next incision is made along the line of attachment of the terminal fibers of the latissimus dorsi to the erector spina and lumbar fascia and this portion of the latissimus dorsi is freed and transferred to the outer margin of the wound. The lumbar fascia or strictly the transversalis aponeurosis is completely exposed when the lumbar portion of the latissimus dorsi is thus transferred to the outer margin of the wound. The lumbar fascia is now incised at its upper portion or superior triangle immediately below and parallel to the twelfth rib. This incision is extended as necessity demands. The lower area of the transversalis portion of the intra abdominal fascia is thus exposed, where it divides to form the fascial capsule of the kidney and the last dorsal nerve is seen following close to and parallel with the inner margin of incision.

In the upper angle of the lumbar fascial incision the retrorenal or posterior layer of the fascial capsule is seen and incision of its posterior layer exposes the fatty capsule through which the kidney is directly approached by blunt dissection. The fatty capsule is now separated by the finger from its attachment to the kidney, excepting about the poles where the finger is hooked into the remaining tissue of the capsule and one or the other pole directed toward the wound. When the kidney is delivered the remaining attached portion of the fatty capsule is freed and both kidney and ureter examined carefully.

A crescentic incision of the fibrous capsule is now made. This incision begins practically on the convex surface near the upper pole, extends on the posterior surface of the kidney to within about one centimeter of the hilum and continues to the convex surface near the lower pole. Two sustaining sutures of silk worm gut, kangaroo tendon or chromic gut are now passed completely around the kidney, one about the lower and one about the upper pole. They are passed in the following way. The one surrounding the lower pole penetrates first the free portion of the fibrous capsule near its juncture with the kidney and about one half inch from the center of the convex border. In its course around the kidney it penetrates the anterior surface of the fibrous capsule midway but only sufficiently to keep it

in place. It is now passed around the inner or concave border close to the lower limits of the hilum and then through the attached portions of the fibrous capsule remaining on the posterior surface. The suture encircling the upper portion is passed in like manner and the ends of these sutures are clamped to keep them in position until the kidney is replaced. Three or more small catgut sutures penetrate the margin of the freed fibrous capsule. These are used after the kidney is returned to anchor this portion of the capsule to the under surface of the lumbar fascia.

None of the fatty capsule except such as may remain attached to the lumbar muscular area is removed. As a rule all of the fatty capsule is forced below and in front of the kidney when the organ is replaced where it is retained by the anchored fibrous capsule. The inner ends of the sustaining sutures are now passed in the upper angle of the wound through the lumbar muscles penetrating them well to the inner side of the last dorsal nerve and out through the skin. The outer ends are passed through the muscular tissue immediately below the twelfth rib and out through the skin. The several catgut sutures which are attached to the margin of the freed fibrous capsule are now anchored to the under surface of the lumbar fascia near its cut edges. The freed fibrous capsule being thus anchored to the under surface of the fascia acts like a shield to prevent the fat in the immediate region from being forced between the posterior surface of the kidney and the quadratus lumborum.

The fascial or aponeurotic incision is now closed with No. 1 or No. 2 plain catgut sutures care being taken to avoid the last dorsal nerve which can be plainly seen crossing the inner margin of the wound. One or two interrupted catgut sutures may be necessary to approximate the fibers of the transversalis and internal oblique muscles. The latissimus dorsi is now returned to its position and its cut edges sutured to its original line of attachment with a continuous plain catgut suture No. 1 or No. 2. The subcutaneous structures are approximated by one or two interrupted catgut sutures and the skin edges united by any method preferred. The sustaining sutures at the upper angle of the wound are tied over a small roll of iodoform gauze, the lower suture being tied first so as to elevate the kidney as much as possible. If kangaroo tendon or chromic gut be used for the sustaining sutures they can be brought out through the skin or not as desired by the operator.

Post-operative care extends over three weeks. In dressing the wound care should be taken not

to restrict the motion of the chest or abdomen. It is usually not necessary to redress the wound until the seventh day. The skin sutures are removed on or after the twelfth day. The silk worm-gut sutures are cut to the inner side of the loop on the nineteenth day and the patient allowed to get out of bed and sit in a chair. This is more advantageous and comfortable than sitting with the limbs extended in bed as the abdominal contents are less crowded. She is encouraged to walk on the following day and on the twenty first the silkworm-gut sutures are gently pulled upon. If they do not come away easily force is not used. The patient is encouraged to walk about and gentle traction is again made on them in a day or two.

The severing of the terminal fibers of the latissimus dorsi along their attachment to the erector spinae and the lumbar fascia and the transferring of the lumbar portion of this muscle to the outer boundary of the wound permit of a complete exposure and easy access to the upper portion of the lumbar fascia or superior triangle. This temporary removal of the muscle from the direct line of approach to the kidney not only facilitates deep manipulation but affords an opportunity for the selection of the direction of the fascial incision. The latissimus dorsi is usually larger on the right side than on the left, owing to the fact that most people are right handed. When this muscle is not well developed, considerable care must be used in severing its fibers near their lumbar attachment so as not to open the sheath of the erector spinae nor cut the lumbar fascia immediately below. The fibers of this muscle in the lumbar region are usually attached in greater part to the sheath of the erector spinae, but it occasionally happens that its inner one-half or more is attached to the lumbar fascia only thus leaving a considerable part of this fascia uncovered by muscle. When the lumbar fascia is incised in the general direction of the erector spinae, as is commonly done, the nerves and blood-vessels which lie immediately below and which run nearly at right angles to the incision are necessarily subjected to great risk of injury but when the fascia is incised immediately below and parallel to the last rib we approach the deeper structures of the outer side of the last dorsal nerve. This nerve follows closely the lower border of the twelfth rib for a short distance, then changes its direction slightly. Its average distance from the rib in the lumbar fascial region is about one centimeter. The nerve is easily located under the fascia on the inner side of the incision and close to its edge and as

its divergence is in the general direction of the pelvis a continuation of the incision outward into the transversalis and internal oblique muscles can be made to any required extent without fear of injury to it unless there exists an abnormality. If it is desired to enlarge the incision inward the lower border of the rib must be followed closely.

During operation the nerve is practically always within view and easily avoided when passing the silkworm-gut sutures through the muscles and when closing the fascial incision. Exceptions to this course of the nerve may be met with, that is, the nerve may follow closely the twelfth rib its entire length necessitating great care in avoiding it when enlarging the incision and when passing sutures through the outer portion of the wound. I have encountered this abnormality twice. The importance of avoiding the nerve cannot be overestimated, as injury to it is often responsible for painful sequelae. The last dorsal, the iliohypogastric and the ilio-inguinal nerves are encountered in most methods of approach increasing thereby the chances of nerve injury. Post-operative pain and diasthesia along the iliohypogastric nerve in the gluteal region, pain in the outer side of the thigh and hyperesthesia along the course of the iliohypogastric nerve have been frequently observed following the technique of approach through the lumbar fascia at a right angle to the general direction of the nerves of that region and therefore constituting a serious objection to this method of approach. Since adopting the present technique of approach post-operative nerve symptoms have been materially lessened.

The only arteries of any size encountered in this technique are sufficiently small to be controlled by forceps pressure and are encountered usually when in the lower angle of the wound, as the aponeurotic or terminal fibers of the latissimus dorsi are severed and the other in the upper angle of the fascial incision when the incision is extended to involve the lower digitation of the serratus posterior inferior.

On replacing the kidney the posterior portion of the fatty capsule is removed if any of it remains attached to the lumbar muscular area, as its presence there will interfere with the proper apposition and union of the surfaces to be apposed. The remaining portion of the fatty capsule is forced anterior to the kidney and maintained there until the fibrous capsular flap is anchored to the under surface of the lumbar fascia. The fat is in this way prevented from wedging between the kidney and the lumbar area.

Fig. 1. The recter spine and lumbi are shown at the bottom of the wound. The lumbi above the latissimus dorsi are in the second step with the peritoneum severed along their attachment to the erect aponeurotic margin of the wound.

Fig. 2. The initial incision in the lumbar region is shown. The lumbi are in the second step with the peritoneum severed along their attachment to the erect aponeurotic margin of the wound.

to which it is to be fixed. When the denuded posterior surface of the kidney is in this manner apposed to the aponeurotic covering of the quadratus lumborum and union between them takes place there is established a condition of the kidney closely approaching normal namely stability with limited mobility.

By following the technique herein described the possibility of injury to the lat dorsal nerve and its blood vessels is eliminated unless their location is abnormal and even then by careful manipulation serious injury can be avoided. Opening into the peritoneal cavity is impossible excepting when the liver or spleen is prolapsed and mistaken for the kidney. In passing the sustaining sutures about the poles care should be taken to discover and avoid the ureter and the renal vessel. In delivering the kidney from the wound we sometimes encounter an accessory artery passing through the fatty capsule and entering the kidney usually near one of its poles. This is recognized first by the greater resistance it offers as compared to that offered by the fatty capsule alone and also by its pulsation. The artery should be secured by a forceps before further attempt is made to deliver the kidney. With ordinary surgical care the delivery procedure should entail no danger.

It possesses the advantage of permitting a thorough preparation of the kidney and allowing a complete examination of the organ and upper

urinary tract and affords an easy approach through the pelvis to the ureter for the removal of all its complications be discovered.

In replacing the kidney the lower part should as a rule be turned first. If difficulty be met with it is usually due to the intraabdominal fascia offering an additional obstruction at the lower angle of the wound. To facilitate replacement the fascia may be further incised or retracted usually it is only necessary to grasp the cut edges of the fascia with a forceps in the angle and gently force the pole through the fascial incision.

Though the anatomy of the lumbar region is familiar to every surgeon the functions of the structures about the kidney with respect to the support and mobility of the organ are very indeterminate. The kidney is afforded its chief protection from external influences by the pinal column the great back muscles and the lower ribs. Within their boundaries there is a well-defined space in which the kidney rests. The fascia varies in depth with the sex and in different individuals of the same sex. Any influence which restricts the free motion of the upper abdominal and lumbar regions as for instance tight lacing tends to force the kidney out of the fossa and subject it to the depressing influence of force from above. The fascia is therefore an indirect factor in the maintenance of position. The kidney has no ligament strictly speaking but is completely surrounded by a strong fascial structure. The fascial structure of capsule is but a part of

Fig. 3. The fascial incision extended in hanging in the lower angle, the internal oblique and transverse abdominis muscles.

the great intra-abdominal fascial system which is so wonderfully arranged as to render vital support to practically every abdominal organ and out of which most of the so-called ligaments of the abdominal viscera are formed. The renal arteries and veins render no support while the kidney is in normal position. These vessels support the kidney and restrict its mobility only when it is forced beyond its normal range of motion which motion does not exceed in any direction, three centimeters.

The fatty capsule or perirenal fascia is composed of a posterior and anterior layer. Superiorly and outwardly these fascial layers are continuous inferiorly and inwardly they do not blend and can be easily separated by blunt dissection. Inwardly they surround the renal vessels as far as the spine, where the posterior layer terminates and is attached and the anterior layer blends with the corresponding layer of the opposite side. Inferiorly they surround the ureter and their failure to unite in this direction constitutes an essential weakness in the scheme of renal support. The posterior layer also called the retrorenal fascia, is intimately attached to the fibrous arches for the psoas and quadratus lumborum to the twelfth rib in this immediate vicinity the first and second lumbar vertebrae and the diaphragm. As the upper and outer portions of the anterior layer are continuous with the corresponding portions of the posterior layer and the posterior layer is fixed to stable points of the anatomy the stability of the anterior layer is greatly dependent upon the fixity of

Fig. 4. The fatty capsule open kidney seen at the bottom of the wound. (Photograph unsuccessfully retouched.)

the posterior layer constituting a most important factor in renal support.

Between the kidney and the fatty capsule there is a network of areolar tissue in the meshes of which is deposited fat constituting the tunica adiposa. This so-called fatty capsule renders support to the kidney to which it is attached only as it is in turn supported by the fascial capsule to which it is also attached. The fatty capsule renders support to the kidney only within the limits of the fascial capsule that is if the fascial capsule were detached from its fixed points of support the kidney with its capsules would prolapse and be limited in descent or motion by the resistance of the renal vessels alone but if the fascial capsule remains fixed and the tunica adiposa be completely severed from its attachment to the kidney the kidney would then prolapse within the limits of the fascial capsule.

Morris cites that in the infant the fatty capsule does not exist and it is the peritoneum which is the chief agent giving fixity to the kidney. The conclusion to be drawn here is that with or without the fatty capsule the peritoneum is an important factor in supporting the kidney. To my mind the resistance afforded by the peritoneum *per se* and the support it renders the kidney in infant or adult is practically inconsiderable. The peritoneum is attached to the intra-abdominal fascia from which is formed the fatty capsule and its stability is dependent upon the stability of this fascial capsule.

Edebohl remarks that in the early operations of nephropexy the idea dominated that the kidney ought to be anchored as high up as possible

Fig. 5. Thickened retroperitoneal fat capsule which has been forced into the retroperitoneum. (The retroperitoneum is present.)

Fig. 6. A resultant incision of the retroperitoneum. The posterior surface of the kidney is exposed from the pole of the retroperitoneum.

under the ribs. The fact was not sufficiently recognized and appreciated that it is the mobility of the kidney which gives rise to the symptoms and that the latter will be perfectly relieved by anchorage of the lower organ even at some distance from its normal habitat. The attempt to realize the ideal inspired the practice of anchoring more or less of the lower end of the kidney only leaving the untouched pole to project upward beneath the ribs. This lead in many cases to either anteversion of the upper pole or to the crowding down of the kidney and often resulting in the return of the old symptoms. Again he states that the kidney cannot be fixed in its normal position and should be fixed squarely in the loin. The middle part fills the lumbar spaces the upper part projecting as far upward beneath the rib as the lower pole reaches downward below the level of the crest of the ilium.

The practical result of the technique that I follow as well as experimentation upon the cadaver have demonstrated that the kidney can by surgical means be placed in the immediate region of its normal habitat the only exception being when the liver or spleen are also considerably prolapsed and enlarged for by occupying the kidney region they crowd the organ and may prevent it from assuming its normal position. With no obstruction in the upper lumbar region the elevation of the entire organ is ensured by tying the suture encircling the lower pole first. The tying of the upper suture next ensures the position of the upper pole and the mobility of the organ.

When the heath of the quadratus lumborum

is opened its entire extent and the muscular fibrous layer had been advised by Edelbohl it is difficult to prevent injury to the nerves and blood vessels of the region if they are immediately in front of the muscle. Fixation of the kidney to the muscle causes an abnormal relationship and every motion of the muscle imparts motion to the kidney and every force acting on the kidney must act correspondingly on the muscle. The function of the nerves and vessels are likewise frequently interfered with by such intimate and abnormal fixation but union of the kidney to the fascial and aponeurotic structures covering the quadratus lumborum would in no way interfere with functioning of the muscle nerves or blood vessels. The only preparation of the muscle area in the technique which I advocated is the removal of the retrorenal fat if any remain attached to this area.

According to Edelbohl the broader the surface for union the stronger will be the anchorage. He in common with all others aimed to fix the outer or convex surface of the kidney to the anterior plane of the quadratus lumborum. In so doing he made an extensive denudation of the kidney surface but this stripping back of the capsule beyond the limits of the convex surface does not increase the area to be apposed for fixation. In width this surface is usually no more than two and one half centimeters and because of its considerable convexity its middle one-third only can be well apposed to the flat surface of the muscle. The posterior surface of the kidney presents the least convexity and greatest expanse for apposition and if the question of permanent anchorage resolves itself into the question of the extent of the surfaces apposed there is left no room for argument as to which surface of the kidney is the surface of choice.

Another objection to fixing the kidney by its

Fig. 7. Three V. O. chromic catgut sutures penetrate the margin of the freed portion of the fibrous capsule. After the kidney is replaced these sutures are used to anchor this fibrous flap to the under surface of the lumbar fascia, where it acts as a shield to prevent the fat from entering between the kidney and the quadratus lumborum.

convex surface is that when so fixed the hilum is forced forward and out of its normal and anatomical relationship. However, when the posterior surface, which is slightly convex, is apposed to the concavity of the lumbar region, the hilum is directed inward and its anatomical relationship restored. Resting thus on its posterior surface the kidney occupies less space anteroposteriorly than when fixed by its outer surface, and assuming thus a protected position in the lumbar fossa according to Nature's plan, escapes force from above as when a coin placed in the palm of the hand escapes the influence of a brush passed over it.

The principles of nephropexy advocated by Billington are open to several objections. The suspension is made in part through a flap of the fibrous capsule stripped from the upper half of the convex and posterior surface. Additional support is rendered by two Brodel sustaining sutures inserted in the attached fibrous capsule covering the lower one half of the convex surface. The fibrous flap, the base of which is attached to and crosses the center of the convex surface is passed up and out between the eleventh and the twelfth ribs and attached to the lips of the fascial incision. The Brodel sutures are tied first being inserted in the attached portion of the fibrous capsule on the lower half of the convex surface direct and fix this area to the posterior wall. The position occupied by the kidney when

Fig. 8. The three catgut sutures with chromic catgut sutures are here shown anchoring the kidney, also the three fibrous capsule turn.

so suspended is on a line external to the outer margin of the rectus spina and the middle of the convex border is on a level with the twelfth rib while the hilum is directed forward. This position of the kidney is not normal and the organ becomes to a dangerous degree exposed to force from above. In Billington's technique no provision is made to support or even limit the motion of the upper pole so that this pole is free to move in whatever direction influenced. Under these circumstances a displacement of the upper pole is always possible when vomiting or coughing are severe and persistent. The organ is therefore liable to topple over or antevert and produce a twisting of its pedicle. Also when the liver is enlarged or is prolapsed much below the twelfth rib it is practically impossible to adopt Billington's technique.

The technique advocated by Longyear fails also to ensure the normal replacement of the kidney and as the position of its upper pole is not

Fig. 4. The lower abdominal wall is closed. The skin and muscle sutures have penetrated the muscles and skin and are seen emerging near the upper angle of the skin incision. The retrocolic but unsutured kidney.

ensured the kidney may likewise antevert and produce a twisting of its pedicle. Longueur's technique possesses one possible advantage and that only when the anterior layer of the fascial capsule has been considerably stretched by the prolapsed kidney his technique fixes the cellular structure termed by him a renocolic ligament which connects the lower anterior surface of the kidney with the anterior layer of the fascial capsule. To which on its peritoneal side is usually attached the colon and in so doing may elevate to some extent the colon. But the cellular structure of the fatty capsule is a structure of little resistance and the permanency of the apposition may be considered doubtful if it is dependent upon this structure. The area of the anterior layer of the fascial capsule to which the colon is attached is located near the spine and as this layer of fascial capsule blends with the corresponding layer of the opposite side and is attached to the tissues of the spine it is rendered more stable than the middle portion. In prolapse of the kidney it is usually the middle portion of the anterior fascial layer which yields. Cases are not uncommon however where the prolapsed organ follows the line of fascial cleavage in the direction of the ureter where the failure of the layers to fuse constitutes a weakness in Nature's scheme of kidney support.

When the kidney is fixed by the technique which I advocate the constant pressure on the anterior layer of the fascial capsule is relieved. The released fatty capsule placed anteriorly must

Fig. 5. The kidney undischarged and the silk worm gut sustaining suture tied over a roll of iodoform gauze.

again attach itself somewhere and can attach itself nowhere but to the stable kidney. The overstretched fascial capsule relieved of the weight of the kidney returns to its normal condition and position. If however it is considered necessary or desirable to fix the lower cellular tissues which are indirectly connected to the colon it can be accomplished during the operation by passing one or more sutures through it and anchoring them to the lumbar fascia when closing the fascial incision.

SUTURE MATERIAL

I prefer the use of the silk worm gut as a sustaining suture to chromic gut or kangaroo tendon because the power is constant while that of the absorbable diminishes in strength daily. With the use of the silk worm gut the maintenance of the kidney where placed is ensured until sufficient time has elapsed for strong union of the surfaces apposed. With the use of the absorbable materials there is no certainty of this apposition remaining when force is exerted from above such as may be caused by deep breathing, persistent coughing or vomiting.

The objection has been made to silk worm gut that it is likely to cut the kidney surface. This objection is only theoretical as in my experience such has never occurred. The sustaining sutures do not touch the kidney proper it being protected by the attached portion of the fibrous capsule on its entire surface. It is necessary that the silk worm gut sutures be carefully selected and that they be of large size and smooth as points of

roughness make their removal difficult. Such an experience I have met with twice in each instance great care and patience had to be exerted. In one of these cases more than a week of gentle traction daily was required and on removal of the gut it was discovered that extensive corrosion at several points had taken place. The black dyed is not desirable as it is friable. Plain or vegetable dyed is to be preferred.

The arguments advanced in favor of silkworm gut apply equally to silver wire the latter possesses the additional advantage, however of never becoming rough. The chief objections to its use are that it is not always conveniently obtained and that if the loop has in it a kink, the removal of the suture may be difficult and painful.

The absorbable sutures are less objectionable as sustaining sutures if they are brought out of the body and tied over a roll of iodoform gauze as is done with the non-absorbable. By this technique the burying of the knot in the tissue is avoided. Nature is usually capable of contending with these knots but she sometimes fails.

DRAINAGE

Drainage is never necessary excepting perhaps where a stone is removed at the time of nephropexy. If a stone be removed from an incision in the pelvis of the ureter the direction of the drain should be from the area between the pelvis of the ureter and the muscles of the back along the lower pole and through the lower angle of the lumbar fascial incision. It should then penetrate the fibers of the latissimus dorsi immediately above and pass out through the corresponding opening in the skin. If the stone be removed through an incision in the cortex, the drain is

Friable silkworm gut has been tried, but without satisfaction, as the tissues become entangled in its fibers and render its removal difficult.

in the same direction as described, but leads from the convex border only. When the cortex is cut in removing a stone, the sutures encircling the kidney assist materially in apposing the cut surfaces and in checking hemorrhage.

In both pyelotomy and nephrotomy nephropexy should at the same time be done. This can be best accomplished by the technique here advocated because in so doing the kidney is suspended at its greatest possible elevation and consequently thorough drainage is ensured to the distended pelvis or pus cavities.

SUMMARY

1. This approach to the kidney necessitates the least injury to the tissues encountered and facilitates deep manipulation.

2. In closing the wound only a minimum amount of the simplest suture material is required and the replacement of the tissues is absolutely anatomical.

3. The kidney area exposed for attachment is the most extensive surface available and so situated as to permit the kidney being anchored in normal anatomical relationship.

4. The sustaining sutures encircling both poles ensure immobility until firm union has taken place and their high placement in the tissues of the back ensures a practically normal position of the organ.

A METHOD FOR PREVENTING AND CONTROLLING HEMORRHAGE FOLLOWING PROSTATECTOMY

By I. H. COOK, M.D., BUFFET, INDIANA

PROSTATECTOMY may not be followed by severe hæmorrhage; bleeding may be slight or severe and readily controlled by one of the various procedures ordinarily applied. But in some instances it may be alarming especially in the aged when the loss of blood and the accompanying shock greatly lessen the chances for recovery. In addition to the means that have been suggested and already applied the following device seems to me to possess advantages that would be of value when hæmorrhage becomes severe or difficult to control.

A catheter of good size is passed into the bladder and drawn out through the opening at the fundus a strip of gauze about one and one half inches in width and of sufficient length as may be required to make a pack approximating the size of space to be packed is wrapped around and above the opening of the catheter by two or three stitches coming out at the side of the catheter over the gauze and tied the first knot being drawn down snugly to the gauze. Before tying the second knot a thread of sufficient length to be drawn out of the bladder wound along with the end of gauze strip is placed over the first knot when the second knot is tied. The thread

making the tie is then cut close to the knot. Two or three such threads are placed each long thread and strip of gauze is held when the catheter with the ring of gauze pack is drawn into the bladder down to the bleeding area sufficient traction being made to secure coaptation of the denuded surfaces thus obliterating the space occupied by the prostate. When the danger from hæmorrhage has subsided traction is made upon each thread thereby releasing the second knot. Traction upon the protruding end of the gauze releases the first knot and unwinds it from the catheter permitting its easy withdrawal from the bladder. The drainage or irrigating tube is placed to be removed when desired.

The gauze pack applied in the manner described not only serves in controlling and preventing dangerous hæmorrhage but also serves to replace the torn and overlapping bladder wall holding the denuded surfaces in place and to early union of the parts separated by the operation rendering unnecessary the frequent hot water irrigation used by some operators a means of controlling hæmorrhage that is not only painful to the patient but adds to shock from frequent disturbance.

A PAINT BRUSH DRAINAGE TUBE

By A. MERRILL MILLER, M.D., F.A.C.S., DANVILLE, ILLINOIS

FOR some time past the split rubber tube has found favor for use in cases requiring drainage.

The objection to its use in the abdominal cavity is the danger of necrosis of soft tissues by the hard unyielding end. To overcome this objection and retain the advantage of the tube I use a tube splitting the entire circumference an inch or more in its long axis. The small rubber

terminals thus made will not cause pressure necrosis and will readily adapt themselves to changing positions of the abdominal viscera (see illustration).

BOOK REVIEWS

A CRITIQUE OF NEW BOOKS IN SURGERY

B. MAJOR G. SEELIG, M.D., S. LUTZ

THERE is something subtly deadening in reading with the fixed purpose of criticising—something that is not categorically different from the state of mind of the modiste as she surveys the new spring styles. If one cannot successfully lose the thought that he is a critic, he finds himself inevitably snared in a maze of data, which though foisted down purely for purposes of criticism, confuses his sense of appreciation and clear reasoning. This is particularly true of medical books. Medical theory and practice is in a state of constant flux; there is so very little that may be expressed in warrantably *ex cathedra* fashion, and by contrast so very much that is promulgated with the seal of authority affixed that one subconsciously finds himself holding his mind open to mere details worthy or unworthy upon which to rest his criticism.

On the other hand, if one reads for the simple joy of reading unimpaired of opinions that may be crystallizing in his own mind as he reads, he finds that each volume makes a totality of appeal to his judgment. He sees and feels what he otherwise would have failed to see and feel. Good reading, like good painting, should be done with the thought of perspective and proportion always in mind.

There is a central idea of purpose in practically every volume published. The art of the critic lies in furnishing sane comment on this purpose, or in pointing out the failure or success of the author in making his purpose clear. Of course in doing this, details must neither be elided nor lost sight of; the reviewer should bear in mind merely that if he dissociates himself from the large purpose of the book, and centers his critical attention unduly on details, he will too often find himself not seeing the forest for the trees.

Let us go through the books of the month with the notion in mind of the impelling motive that is responsible for each volume. Whatever there may be said regarding the value of this type of critique no one may say that it is lacking in interest.

THIS volume on *Autoplastic Bone Surgery* illustrates most admirably exactly what we mean by the phrase central idea of purpose. One does not need the statement in the preface of the book to convince him that the authors have had their interest awakened from three different

Autoplastic Bone Surgery. By Charles Dwyer, M.D. and Franklin D. Smith, M.D. Philadelphia and New York: Lea and Febiger, 1926.

directions: experimental bibliography and clinical. There are no concrete statements in the text emphasizing the fact but one knows nevertheless, that the authors felt the inner drive to aid in clarifying a surgical topic that is just now in process of evolution. Such purpose is worthy, and it is gratifying to be able to note that accomplishment has kept pace fairly well with purpose.

The book does not differ markedly from its sister volume written almost synchronously by Albee and recently reviewed in these columns. A careful survey shows that in spite of a different arrangement of chapter heads, the same subjects are treated in much the same fashion with the normal diversity of opinions that one would expect to meet in most subjects of this type. The general topics of bone transplantation, periosteal regeneration, indications and technique, autoplastic repair of fractures, rhytidoplasty, autoplastic immobilization of spondylitis and of congenital bone defects are all accorded due space. The chapters on periosteal regeneration of bone and regeneration of bone are written with almost didactic clearness, each chapter ending with a clear, crisp summary of the fundamental facts.

It is interesting to note that the indications for bone grafting furnished by Davidson and Smith tally almost with letter with the indications set by Albee. One is also struck by the fact that these authors have seen the wisdom of doing what Albee failed to do, namely, appending what seems to be a very full and accurate bibliography.

Anyone who has followed this new chapter of bone surgery closely, mindful of the great diversity of opinion so discernible since the publication of McCraw's book, *Growth of Bone*, will naturally hesitate to take sides with or against the authors on any doubtful question. The thing of significance and interest is that the purpose back of the book has resulted in furnishing us with work of practical importance from the academic as well as from the purely technical point of view. We have said before in these pages, that the good monograph is the lodestone of the library. This volume serves to strengthen that opinion.

THIS next book by Dr. Crile has in some inexplicable way reached the reviewer's sanctum about one year late. The delay is in a

Voice Association. By George B. Crile, M.D. and William E. Lower, M.D. Philadelphia and London: W. B. Saunders Company.

sense fortunate for had the book reached us on schedule time we would have felt obliged to paraphrase the doctrine of anoci-association comment on its scientific basis dilate upon the weakness and strength of Crile's methods. In short fuse the new doctrine in the crucible of criticism. Now for unluckily all this has been done for us. It is pretty safe to assume that those who do not feel what William James used to call the sense of personal warmth of knowledge of the anoci-association theory do not read ST. CLARE GAYNE HUGHES ON STRENGTH. We are free therefore to play with the thesis of the month and content ourselves solely with interpreting the purpose back of Crile's work.

And lest our judgment appear colorless and ultra-judicious it is necessary to say at the outset that we feel that the recent severe criticism of anoci-association by Carlson even though it took on somewhat the form of a polemic, was in good part justified. This is unfortunate and equally unfortunate is the fact that many of Crile's conclusions do not flow from well-constructed syllogisms but seem to be revelational.

If one dismisses for the time being all such broad generalizations as the above he unavoidably centers on the drive back of the work the enthusiastic, determined effort to popularize a doctrine. And however much one may take issue with the so-called pure science of the work or how ever spiritedly he may cavil at the all too comprehensiveness of Crile's inclusions he must nevertheless feel the weight of sincere effort represented by the large amount of experimental data collected over a long period of time.

The presentation of this mass of experimental data marks only one half of the purpose of the book—it stands as the academic purpose. Much more important are the advantages that have accrued to surgery. These latter results constitute the practical workaday purpose of the doctrine. Beyond all question of doubt Crile has ingrained a spirit of surgical gentleness in the consciousness of countless surgeons. Careful selection of operative material gentleness of manner deliberate and thoughtful precision of a closely related fusion of individual efforts—these are things that have resulted directly from Crile's magnetic rays written and spoken, and I for one am content to let such things tip the balance against the load of somewhat faulty logic. In other words I am inclined to pass over the conflict of testimony and to experience a deep sense of gratitude for what the doctrine of anoci-association has done for surgery from the crass practical point of view.

In this volume Smithies has collected the largest amount of clinical data offering the greatest number of intensively studied stomach cancers

that I have ever seen grouped between two covers. In reality the book comes under the head of monographs but bulk form thoroughness and wealth of illustrations force one to group it under the head of treatises.

The plan of the book excellent throughout rests on a carefully developed chapter division of twelve parts. Each chapter in its turn is based upon the personal experience of the author and then rounded out by a critical selection from literature of data bearing on the various important topics discussed. It is impossible to overestimate the value of this method of exposition. For example in Chapter XIII on Gastric Cancer in the Young Smithies not only analyzes in minute detail eighteen such cases of carcinoma studied by him but also furnishes his reader with the references necessary for a broad conception of this most interesting though limited topic. Welch Osler McCrave and Dock.

Chapter I General Distribution and Etiology furnishes nothing new but it well presents in rather extended fashion much valuable data collected from various credited sources. Chapter II on Morbid Anatomy is notable chiefly for the large amount of pathological material, and the care with which it has been studied. Excellent and painstaking as has been the work of MacCarthy it hardly justifies Smithies' statement that to it we we practically all our useful knowledge regarding the early histologic changes which are associated with the development of gastric cancer. The notable point in Chapter III Symptomatology is the radical and yet rational (though we must concede Utopian) hope expressed by the author that the early diagnosis of cancer of the stomach must be made microscopically from a bit of freshly removed tissue. This chapter is particularly full embracing as it does quite a number of illustrative case histories. Chapter IV deals with physical signs under the questionable title of Physical Abnormalities. In this chapter Smithies very wisely dilates upon those signs (he enumerates seven of them) which determine the inoperability of gastric malignant neoplasms. Chapters V VI and VII deal in order with the clinical microscopy of gastrointestinal function roentgen examination and blood changes in gastric carcinoma. That portion devoted to roentgen examination is only fairly well illustrated the plates are by no means as good as the recently published ones in the work of George and Leonard. It is necessary to emphasize this fact because a poor reproduction of an X-ray plate is worse than useless. Chapter VIII the Significance of Gastric Ulcer with Respect to Gastric Cancer suffers somewhat by reason of its highly statistical character. We should have preferred a more condensed and concentrated arrangement of the statistics followed by a more distinctly personal statement by the author of his own interpretation of the figures. Chapter X Differential Diagnosis is the weakest chapter of the book. No further

NOTE OF THE STOMACH. A LINGUA. STUDY OF 92 OTHER STOMACHES. MED. WITH CHAPTER ON THE SURGICAL TREATMENT OF STOMACH. BY ALBERT J. SCHLESER. M.D. L.D. IN A. Philokipia. and London W. H. Saunders. Comp. by G. D.

support of this criticism is necessary than the mere mention that Smithies does not even suggest pernicious anemia or tuberculosis in any of his differentiations. If one calls to mind the chapter on differential diagnosis in Schmidt's book on *Tumors of the Abdominal Viscera* he will at once appreciate how far short Smithies has fallen. The final chapter on the non-surgical treatment of cancer of the stomach is admirably done and constitutes a most valuable part of the volume. It is unfortunate that Smithies, in describing the technique of transfusion in inoperable cases, describes the method as the Percy-Cook method. The credit should go to Kilmpton to whom it properly belongs. The chapter on the surgery of gastric cancer written by Dr. Ochsner is adequate and particularly well illustrated. One misses, with regret, any mention of the recently proposed Polya method of gastric resection. Comment on this operation by Ochsner would have been particularly valuable.

On the whole the book fulfills its purpose well in demonstrating the value of an intensive, well correlated study of clinical material. The only thing lacking is just a bit more of Smithies himself for the sake of color and interest. A strongly personal note adds conviction as well as salt and spice to a book. On pages 67 and 68 the author rises in righteous wrath against the fox trot bunny hug consists *et al* and states in most unequivocal terms his own ideas regarding what constitutes proper physical examination. We should have enjoyed a thicker tudding of the volume with this same style of writing.

THE new third edition of Edwards' *Practice of Medicine* has been reviewed for us by Dr. Mandel in the following words:

"The book is practically rewritten and rearranged to conform with the more recent classification of diseases. Much new matter has been added. Especially commendable is the space devoted to diagnosis. The differential diagnostic tables covering diseases of the heart, liver, kidneys, blood states, etc. are complete and practical and should be of value to the student and teacher. Surgical indications in border line cases, statistics, medical and surgical, and the extensive bibliography enhance the value of this new work and create a special appeal to the surgeon.

"Treatment is outlined in great detail. This is particularly true in the treatment of cardiac insufficiency, syphilis and tuberculosis. The dietetic treatment of nephritis and diabetes approaches in completeness that which we might expect in a work on dietetics. The discussion of the physiological action and therapeutic indications of the more commonly used drugs is another unique and laudable feature of the volume.

In this edition as in the two previous editions the author has succeeded in subordinating the theoretical and eliminating the obsolete, thereby giving us a *Practice* which is complete, practical and up-to-date. An ideal text-book for students, a necessity for the general practitioner and a valuable addition to the library of the teacher.

ADVISORY COMMITTEE OF CIVILIAN PHYSICIANS AND SURGEONS
ON MEDICAL PREPAREDNESS

INFORMALLY it was brought to the attention of a number of civilian physicians that a consulting committee on medical preparedness would be desirable. This resulted in a suggestion that the presidents of the American Medical Association, the American Surgical Association, the Congress of American Physicians and Surgeons, the Clinical Congress of Surgeons of North America, and the American College of Surgeons should jointly appoint an ad interim committee which could co-operate in developing the civilian and reserve medical resources of the country to the highest point of efficiency. As a result of these suggestions the following committee was appointed in the manner indicated: the presidents of the various societies acting as members of the committee:

William J Mayo Chairman Rochester Minn
Frank F Simpson Secretary Pittsburgh Pa
Frank Billings Chicago
John F Binnie Kansas City Mo
Joseph C Bloodgood, Baltimore
George E Brewer New York City
George W Crile Cleveland
J M T Finney Baltimore
Charles L Gibson New York City
Robert G LeConte Philadelphia
Fred B Lund Boston
Edward Martin Philadelphia
Franklin H Martin Chicago
Rudolph Matas New Orleans
Charles H Mayo Rochester Minn.
Lewis S McMurry Louisville Ky
John B Murphy Chicago
Albert J Ochsner Chicago
Charles A Porter Boston
Charles A L Reed Cincinnati
Emmet Rixford San Francisco
Hubert A Rovster Raleigh N C
George E de Schweinitz Philadelphia
Henry Sewall Denver
Richard P Strong Cambridge Mass
William S Thayer Baltimore
Albert Vander Veer Albany N Y
Victor C Vaughan Ann Arbor Mich

This Committee met in Chicago for organization on April 14. Dr William J Mayo of Rochester Minn was elected Chairman of the Committee. Dr Frank F Simpson of Pittsburgh Secretary and an Executive Committee chosen as follows:

George E Brewer	William J Mayo
George W Crile	Franklin H Martin
J M T Finney	Frank F Simpson
Robert G LeConte	William S Thayer
Fred B Lund	Albert Vander Veer

On April 20 the Executive Committee met in Washington and presented in person to President Wilson the following memorandum:

WASHINGTON D C April 20 1916

Dear Mr President—We the under-signed acting as a committee on behalf of four national societies to wit the American Medical Association the Congress of American Physicians and Surgeons the Clinical Congress of Surgeons of North America and the American College of Surgeons representing an aggregate membership of 90 000 medical men have the honor respectfully to present our greeting and to tender to the Federal Government our services toward the medical welfare of the Army and Navy being impelled so to do by the following considerations:

1 In times of peace as well as in times of war the medical profession as above represented holds itself in readiness out of a spirit of patriotism and of co-operation to serve the best interests of the Federal Government

2 The European war especially during its first six months demonstrated a greater need both of medical supplies and of more efficient organization of medical resources, in connection with military and naval activities than was formerly deemed necessary or adequate

3 Every soldier and sailor in the service of the Federal Government is entitled at all times to protection in sanitary matters and to prompt medical and surgical care

Prompted therefore by these considerations the medical profession as above represented respectfully offers its services toward the well being of the army and navy departments. Among the services which at this time the above named organizations specifically tender their co-operation in conjunction with existing facilities of the Army and Navy for such purposes are:

1 To establish through their respective membership and their affiliations with local medical societies of the states and territories an or

ganization that would be in a position to make a comprehensive survey of the medical resources of the country

2 To make a complete invoice of such resources available in peace and in the emergency of war This invoice would include not only the names of men available for field or home duty who are trained in the specialties of medicine surgery and sanitation but it would also include the extensive equipment under the control of these men such as hospital facilities and lists of trained nurses

3 To aid in the public health service in sanitation, quarantine, and hygiene of the troops to aid in the inspection of camps and ports to analyze water sources and supply systems to study effects of climates, exposure, diet etc all designed for the welfare of the individuals enlisted in the Army and Navy Departments

The medical profession as above represented respectfully submits that thorough organization of the civilian and reserve medical resources of the country are of primary importance in the proper preparedness of the country It does not however here and now offer or imply any recommendation as to the national policy for preparedness beyond adequate sanitary medical and surgical protection of those who may be enlisted in the army and navy departments

Respectfully submitted

The General Committee in pursuance of its plan for a general survey of the medical resources of the country has selected a committee in each state to aid in the work These state committees are listed below Members of the General Committee are also members of the state committees in the states in which they reside To the General Committee have been added the following as members ex officio

W C C ORR Surgeon General United States Army

W C BRAINARD Surgeon General United States Navy

Rupert Blue Surgeon General, United States Public Health Service

Colonel Jefferson R Kean

Major Herbert J Nolle

President American Medical Association

President American Surgical Association

President Congress of American Physicians and Surgeons

President Clinical Congress of Surgeons of North America

President American College of Surgeons with the following as Associate Members

Winford Smith M D Baltimore

Eugene Smith Dean Harvard Dental School

Edward C Kirk Dean University of Pennsylvania Dental Department

Thomas L Gilmer Dean Northwestern University Dental Department

J MONTGOMERY BALDY	E E MONTGOMERY	GEORGE E DE SCHWEINITZ
BARTON COOKE HIRST	GEORGE W NORRIS	J E SWEET
WILMER KROEN	FRANCIS R PACKARD	WILLIAM J TAYLOR
EDWARD MARTIN	GEORGE E PFABLER	ALEXANDER A UHLE

PLANS FOR THE PHILADELPHIA MEETING

ON the following pages is presented a preliminary program of the evening meetings to be held during the week of the Clinical Congress of Surgeons in Philadelphia. All of these meetings with the exception of the public meeting on Friday evening are to be held in the Ball Room of the Bellevue Stratford. On Friday evening in Witherspoon Hall located only a short distance from the Bellevue Stratford there will be an open session to which the public will be invited. Questions of great interest to the public will be discussed by men who can speak with authority concerning the problems presented. On three evenings of the week there will be separate meetings for the section on surgery of the eye ear nose and throat the program for which will be published in an early issue. These meetings will also be held at the Bellevue Stratford.

It is evident from the number of registrations already received at the office of the

Secretary General that the limit of membership fixed for the Philadelphia session will be reached within a short time. Bearing in mind that several hundred surgeons who wished to attend the Boston meeting last October were disappointed because their registrations were received too late it is urged upon those surgeons who wish to attend the Philadelphia meeting but who have not sent in their registrations that application should be made immediately to the Secretary General Dr Franklin H. Martin 30 N Michigan Ave Chicago Illinois. When the required number of registrations has been received no further applications can be accepted.

A careful survey of the operating amphitheatres lecture rooms and laboratories of the several medical schools and hospitals in Philadelphia as to their capacity for accommodating visiting surgeons, has been made and the limit of attendance based upon this survey. The

popularity of these clinical meetings has become so great that the plan of limiting the attendance and requiring advance registration was decided upon to prevent overcrowding. This plan assures accommodations at the clinics for all who hold membership cards and has worked satisfactorily at the two previous meetings, in London in 1914 and in Boston in 1915.

THE CLINICAL PROGRAM

The schedule of clinics and demonstrations to be given by the clinicians of Philadelphia during the week of October 23d as published in these pages is a tentative one and is to be amplified and corrected from month to month as the work of the Committee on Arrangements progresses, so that the final program will properly represent the clinical work of the Philadelphia surgeons. The Committee on Arrangements has planned for a complete showing of Philadelphia's clinical facilities in every department of surgery including gynecology obstetrics, genito-urinary surgery orthopedics, surgery of the eye, ear nose, and throat, together with many demonstrations on borderline subjects.

MEMBERSHIP—REGISTRATION FEE

The Constitution of the Congress provides that all subscribers to the official journal *SURGERY GYNECOLOGY AND OBSTETRICS* are members of the Congress and that such other legally qualified practitioners as are in good standing in their own communities may become members upon registering at an annual meeting.

The constitution also provides that a registration fee shall be required of each member attending an annual meeting, there being no annual dues for members of the Congress. The registration fees provide funds to meet the expense of preparing for and conducting the

annual meetings so that no financial burden is imposed upon members of the profession in the city entertaining the Congress.

HEADQUARTERS

Headquarters will be established at the Bellevue-Stratford where the Ball Room, Clover Room, Red Room Green Room, and adjacent foyers and smaller rooms have been reserved for the use of the Congress. These rooms are located on the second floor of the hotel and provide ample space for registration rooms and ticket bureau, bulletin boards, etc. the Ball Room being used for the evening meetings.

Headquarters will be open on the afternoon of Saturday October 21st, and on Sunday the 22d, for the registration of members. The program of clinics and demonstrations for Monday will be bulletined on Saturday afternoon, and on each afternoon, beginning on Monday the complete program for the next day's clinics will be posted on bulletin boards in headquarters. A printed program will be issued each morning and special tickets for all clinics and demonstrations will be issued to members at 8 a.m. each day.

SPECIAL TICKETS

The use of special tickets at previous sessions has fully demonstrated the efficacy of this method of providing for the distribution of members among the various clinics. To prevent overcrowding, tickets for any clinic or demonstration are limited in number to the actual capacity of the room in which the clinic or demonstration is to be given. These special tickets will be issued at 8 o'clock each morning for the clinics and demonstrations to be held that day a complete clinical schedule having been posted on the bulletin board on the afternoon of the preceding day and a printed schedule of the clinics distributed early each morning.

PRELIMINARY CLINICAL PROGRAM

GENERAL SURGERY

Monday

CHARLES H. FRAZIER — University Hospital — 9 to 12
 T. TURNER THOMAS — University Hospital — 3 to 4
 GEORGE C. ROSS — German Hospital — 9
 A. D. WHITE — German Hospital — 10
 JOHN B. DEEVER — German Hospital — 12
 E. G. ALEXANDER — Episcopal Hospital — 10 to 1

Saturday

W. WAYNE BABCOCK — Samaritan Hospital — 9 to 1
 JOHN B. DEEVER — German Hospital — 12
 LEVI J. HUNTER — Methodist Episcopal Hospital — 1
 THOMAS R. NEILSON — Episcopal Hospital — 11 to 3

Days and Hours to be Announced

LEON BREXMAN — St. Agnes Hospital.
 J. CHALMERS DALOWA — Jefferson Hospital.
 HARRY C. DEEVER — Women's College and Kensington Hospitals.
 GEORGE M. DORRANCE — St. Agnes Hospital.
 M. M. FRANKLIN — St. Joseph's Hospital.
 JOHN GIBSON — Jefferson Hospital.
 EDWARD B. HODGE — Presbyterian Hospital.
 JOHN F. A. JONES — St. Joseph's Hospital.
 J. H. JORSON — Presbyterian and Polyclinic Hospitals.
 JAMES A. KELLY — St. Joseph's Hospital.
 ERNEST LAPLACE — Medico-Chirurgical Hospital.
 G. P. MUELLER — St. Agnes Hospital.
 CHARLES NARBAU — St. Joseph's Hospital.
 FRANCIS T. STEWART — Jefferson Hospital.
 WILLIAM J. TAYLOR — St. Agnes Hospital.
 H. R. WHEATON — Presbyterian Hospital.

GYNECOLOGY AND OBSTETRICS

Monday

THEO A. ERCK — Gynecologic Hospital — 10 to 1
 BARTON COOKE HIRST and JOHN COOKE HIRST — Howard Hospital — 11

E. E. MONTGOMERY — Jefferson Hospital — 1 to 1
 C. B. LONG ECKER — Oncologic Hospital — 5
 J. C. HUNTER — Samaritan Hospital — 12 to 1
 F. M. FISHER — St. Agnes Hospital — 9 to 1

SURGERY GYNECOLOGY AND OBSTETRICS

WILLIAM E. TRACY — Stetson Hospital — 9 30.
 WILLIAM D. CULLEN — West Philadelphia General Homeopathic Hospital — 0.
 ANNA STEWART COOKE — Woman Hospital — 9.
 ANNA H. LOCKERY — Woman's Hospital — 0.
 JOHN G. CLARK and staff — University Hospital — 9 to 2.

Tuesday

GEORGE W. OUTERBRIDGE — Gynecean Hospital.
 BROOKER M. ABERNETHY — Gynecean Hospital.
 D. B. JAMES and N. F. LAKE — Hahnemann Hospital — 30.
 EDWARD P. DAVIS — Jefferson Hospital —
 E. MONTGOMERY — Jefferson Hospital — to
 WILLIAM E. PARKER — Kensington Hospital — 1
 W. R. NICHOLSON — Methodist Episcopal Hospital — 9.
 RICHARD C. NORRIS — Methodist Episcopal Hospital —
 JOHN H. GRIVIN and GEORGE E. SCHOENMAKER — Presbyterian Hospital — 1
 WILMER KRUSEN — Samaritan Hospital — to
 JOHN A. MCGILVER — St. Agnes' Hospital — 1.
 P. BROOKER BLAND — St. Joseph's Hospital.
 BROOKER M. ABERNETHY — Stetson Hospital — 9.
 ANTON COOKE HIRST — University Hospital — 9.
 ANNA H. LOCKERY — West Philadelphia Hospital for Women — to 1
 ANNA W. GRIM — Woman Hospital — 9.
 LARIN K. FOREMAN — Woman's Hospital — 0.

Wednesday

THOMAS A. ERICK — Gynecean Hospital — to 1.
 ANTON COOKE HIRST and JOHN COOKE HIRST — Howard Hospital — 11.
 E. MONTGOMERY — Jefferson Hospital — to
 P. DAVIS — Philadelphia General Hospital — to 4.

 MARY T. MILLER — Woman Hospital — 9.
 SARAH H. LOCKERY — Woman Hospital — 0.

Friday

THOMAS A. ERICK — Gynecean Hospital — to
 ANTON COOKE HIRST and JOHN COOKE HIRST — Howard Hospital —
 WILLIAM E. PARKER — Kensington Hospital —
 F. C. HANCOCK — Samaritan Hospital — to
 JOHN A. MCGILVER — St. Vincent Hospital.
 M. LOUISER DILL — Woman's Hospital — 9.
 CATHERINE MACFARLANE — Woman's Hospital — 0.

Saturday

P. BROOKER BLAND — Jefferson Hospital — 1 to
 ANTON COOKE HIRST — University Hospital — 9.
 JOHN G. CLARK and staff — University Hospital — 9 to
 WILMER KRUSEN — Samaritan Hospital — 1 1

Days to be announced

GEORGE M. BOYD — Medico-Chirurgical and Philadelphia Lying in Charity Hospital.

ORTHOPEDIC SURGERY

Monday

T. RUSS and staff — Methodist Episcopal Hospital — 4 to 5.
 B. GILL — Episcopal Hospital — to 5.

Tuesday

I. M. FRANKLIN — Philadelphia General Hospital — to
 T. RUSS and staff — Methodist Episcopal Hospital — 4 to 5.
 I. A. WILSON and staff — Jefferson Hospital — to
 J. T. YLON and staff — Orthopedic Hospital — to
 P. MANK — Medico-Chirurgical Hospital — to 3
 ARRY HUNTER and staff — Samaritan Hospital — to 4.
 G. DAVIS and staff — University Hospital — 1 3

Wednesday

G. DAVIS and staff — University Hospital — to 4.
 T. RUSS and staff — Methodist Episcopal Hospital — 4 to 5.
 B. GILL — Episcopal Hospital — 9 to

Thursday

I. A. WILSON and staff — Jefferson Hospital — to 1.
 G. G. DAVIS and staff — Orthopedic Hospital — to
 J. P. MANK — Medico-Chirurgical Hospital — 1 to 3
 J. K. YOUNG and staff — Polyclinic Hospital — 3 to 5.
 G. G. DAVIS and staff — University Hospital — to 3

Friday

J. T. RUSS and staff — Methodist Episcopal Hospital — 4 to 5.
 G. G. DAVIS — Widener School — 1 4.
 G. G. DAVIS and staff — University Hospital — 1 to 3
 J. K. YOUNG — Philadelphia General Hospital — to 4.
 J. T. RUSS — Philadelphia General Hospital — 1
 DOUGLAS J. MONTGOMERY — Hahnemann Hospital —

Saturday

A. P. C. ABERNETHY and staff — Orthopedic Hospital — 9 to
 I. A. WILSON and staff — Jefferson Hospital — to

ROENTGENOLOGY

M m

- SIDNEY FELDSTEIN — Jewish Hospital — 3 to 4. Oblique and intestinal fractures.
 W S NEW MET — Jewish Hospital — 3 to 4. Bone lesions sinus cases (in conjunction with Dr Stauffer).
 GEORGE E PFUHL — Medical-Chirurgical Hospital — 3 to 4. Roentgen diagnosis in the treatment of deep-seated malignant disease.
 A G MILLER — German Hospital — 3 to 4.

T s d

- DAVID R B WEN — Pennsylvania Hospital — 3 to 4. Fractures.
 FREDERICK C HOLT — 438 N 5th St — 3 to 4. Organ lesions of the stomach and duodenum.
 W F MANLEY — Jefferson Hospital — 3 to 4. Pilocop and peliography.
 W S NEW MET — Presbyterian Hospital — 3 to 4. Bone lesions sinus cases (in conjunction with Dr Stauffer).
 A C MILLER — German Hospital — 3 to 4.
 GEORGE E PFUHL — Medical-Chirurgical Hospital — 3 to 4. Roentgen diagnosis of gastric and duodenal lesions. Lantern slide demonstration.

Wed and

- W F MANLEY — Jefferson Hospital — 3 to 4. Fluoropy of the gastro-intestinal tract.
 A C MILLER — German Hospital — 3 to 4.
 W S NEW MET — Presbyterian Hospital — 3 to 4. Bone lesions sinus cases (in conjunction with Dr Stauffer).
 GEORGE E PFUHL — Medical-Chirurgical Hospital — 3 to 4. Roentgen diagnosis of gall-stones.
 DAVID K BOWEN — Pennsylvania Hospital — 3 to 4. Bone and joint diseases.
 M K FISHER — St Louis Hospital — 3 to 4. Int diseases and radiography of the urinary tract.
 JACOB W FRANK — Hahnemann Hospital — 3 to 4.

Th and

- DAVID R B WEN — Pennsylvania Hospital — 3 to 4. Surgical diseases of the thorax.

- SIDNEY FELDSTEIN — Jewish Hospital — 3 to 4. Tuberculosis of the lungs.
 FREDERICK C HOLT — 438 N 5th St — 3 to 4. Intestinal pathology.
 A C MILLER — German Hospital — 3 to 4.
 W F MANLEY — Jefferson Hospital — 3 to 4. Brain tumor and intra cranial lesion.
 W S NEW MET — Presbyterian Hospital — 3 to 4. Bone lesions sinus cases (in conjunction with Dr Stauffer).

Fri

- DAVID R B WEN — Pennsylvania Hospital — 3 to 4. The management of small and medium sized hospital roentgen laboratories.
 W F MANLEY — Jefferson Hospital — 3 to 4. Roentgen examination of teeth as an aid to surgical diagnosis.
 W S NEW MET — Presbyterian Hospital — 3 to 4. Bone lesions sinus cases (in conjunction with Dr Stauffer).
 A C MILLER — German Hospital — 3 to 4.
 GEORGE E PFUHL — Medical-Chirurgical Hospital — 3 to 4. Electro-coagulation in the treatment of malignant disease.
 M K FISHER — St Louis Hospital — 3 to 4. Int diseases and radiography of the urinary tract.
 JACOB W FRANK — Hahnemann Hospital — 3 to 4.

Sat

- A C MILLER — German Hospital — 3 to 4.
 DAVID R B WEN — Pennsylvania Hospital — 3 to 4. The management of small and medium-sized hospital roentgen laboratories.
 W S NEW MET — Presbyterian Hospital — 3 to 4. Bone lesions sinus cases (in conjunction with Dr Stauffer).
 D J T B E I O W R D
 HENRY K PANCOAST — University Hospital — 3 to 4. Radium therapy of 4 Gastro-intestinal tract.
 W S NEW MET — Jefferson Hospital — 3 to 4. Deep vent geotherapy and radium therapy in advanced cancer cases.

GENITO-URINARY SURGERY

- L F ALCRAFT — Hahnemann Hospital — Tuesday.
 H M CHRISTIAN — Medical-Chirurgical Hospital.
 H R LOUGHEAD — Jefferson Hospital.
 T R NELSON — University Hospital.
 L F ALCRAFT — Women's Homeopathic Hospital.

- E H STIER — Philadelphia General Hospital.
 E H STIER and staff — University Hospital.
 B A THOMAS — Philadelphia Clinic Hospital.
 A A THOMAS and WILLIAM MACKENNEY — German Hospital — Monday and Friday 4 to 5.

LABORATORY DEMONSTRATIONS

- D J T B E I O W R D
 DAVID R B WEN — German Hospital — Monday and Friday.
 W F MANLEY — German Hospital — Monday and Friday.
 DR. APPEL — University of Berlin and Hahnemann Hospital — Wednesday and Friday.
 J F NEW MET — Medical-Chirurgical Hospital — Wednesday.
 Tumor growth and necrosis.

- C B LANE — Oncologic Hospital — Monday and Tuesday 4 to 5. Demonstration of photomicrographs and color plates with special reference to hospital photography.
 G S S — Oncologic Hospital — Wednesday and Friday. Laboratory technique especially new developments in the Abderhalden reaction.

SURGERY OF THE EYE

Monday

WILLIAM CAMPBELL POSEY — Howard Hospital —
 S. LEWIS ZIEGLER — Wills Eye Hospital —
 SAMUEL D. RUSLEY — Wills Eye Hospital —
 McCLENNY RADCLIFFE — Wills Eye Hospital —
 WILLIAM M. SWEET — Wills Eye Hospital — 3
 PAUL POWITUS — Wills Eye Hospital — 2.
 L. PETER — Polyclinic Hospital —
 WILLIAM T. SPOONMAKER — German Hospital —
 PAUL POWITUS — St. Joseph's Hospital — 3:30.
 FREDERICK KRAUSE — Episcopal Hospital —
 LOUIS LOVE — St. Mary's Hospital — 3
 AARON BRAV — Jewish Hospital — 3.
 E. D. FUNK — Jefferson Hospital — 2.

Tuesday

E. D. FUNK — Jefferson Hospital — 2.
 WILLIAM T. SPOONMAKER — Pennsylvania Hospital — 2.
 GEORGE S. CRAMPTON — Pennsylvania Hospital — 2.
 PHILIP H. MOORE — Methodist Episcopal Hospital — 4.
 WILLIAM W. SPRAEDMAN — Habesmann Hospital — 2.
 WILLIAM CAMPBELL POSEY — Wills Eye Hospital —
 P. N. K. SCHWENK — Wills Eye Hospital — 30.
 WILLIAM ZENTMAYER — Wills Eye Hospital —
 T. B. HOLLOW — Polyclinic Hospital —
 MARY BUCHANAN — Women's Hospital —
 G. OZAM KING — Episcopal Hospital — 2.
 WENDELL REIMER — Samaritan Hospital — 4 to 5
 AARON BRAV — Leabson Hospital — 2.
 H. F. HANVELL — Philadelphia General Hospital — to 3
 McCLENNY RADCLIFFE and J. M. GRISCOM — Presbyterian Hospital —
 G. P. FRANKLIN — Stetson Hospital —
 G. E. DE SCHWENCK and J. T. CARPENTER — University Hospital — 3
 G. E. DE SCHWENCK — University Hospital — 3

Wednesday

WILLIAM T. SPOONMAKER — German Hospital —
 CHARLES W. LEFEBVRE and S. J. GETTELSON — Mt. Sinai Hospital — 3.
 E. D. FUNK — Jefferson Hospital — 2.
 L. WENSTER FINE — Medico-Chirurgical Hospital —
 S. LEWIS ZIEGLER — Wills Eye Hospital —
 SAMUEL D. RUSLEY — Wills Eye Hospital —
 McCLENNY RADCLIFFE — Wills Eye Hospital — 3.
 WILLIAM M. SWEET — Wills Eye Hospital —
 PAUL POWITUS — Wills Eye Hospital — 2.
 WENDELL REIMER — Polyclinic Hospital — 2.
 WILLIAM T. SPOONMAKER — German Hospital —
 CHARLES J. JONES — St. Joseph's Hospital — 3.
 MIRIAM M. BUTT — Women's Hospital —
 H. G. GOLDREING — Episcopal Hospital —
 LOUIS LOVE — St. Mary's Hospital — 3

J. C. KRIEPE — Jewish Hospital — 3

JOHN W. CROSBY — Philadelphia General Hospital — 2.
 E. A. SHUNWAY — Philadelphia General Hospital — 3.
 T. B. HOLLOW — H. M. LANGDON and CARL WILLIAMS — University Hospital — 5.

Thursday

PHILIP H. MOORE — Methodist Episcopal Hospital — 4
 J. A. KEARNEY — St. Agnes' Hospital — 3.
 J. C. KRIEPE — Jefferson Hospital — 2.
 E. D. FUNK — Jefferson Hospital —
 WILLIAM T. SPOONMAKER — Pennsylvania Hospital — 2.
 GEORGE S. CRAMPTON — Pennsylvania Hospital — 2.
 WILLIAM CAMPBELL POSEY — Wills Eye Hospital —
 P. N. K. SCHWENK — Wills Eye Hospital — 1:30.
 C. P. F. LYN — Stetson Hospital —
 WILLIAM ZENTMAYER — Wills Eye Hospital —
 L. APPELMAN — Polyclinic Hospital —
 MARY BUCHANAN — Women's Hospital —
 FREDERICK KRAUSE — Episcopal Hospital —
 AARON BRAV — Leabson Hospital — 2.
 JAMES TH. RINGTON and J. M. GRISCOM — Presbyterian Hospital —
 G. E. DE SCHWENCK and E. A. SHUNWAY — University Hospital — 3.
 H. F. HANVELL — Philadelphia General Hospital — to 3

Friday

H. F. HANVELL and WILLIAM M. SWEET — Jefferson Hospital — 45
 S. LEWIS ZIEGLER — Wills Eye Hospital —
 SAMUEL D. RUSLEY — Wills Eye Hospital —
 McCLENNY RADCLIFFE — Wills Eye Hospital —
 P. OL. POWITUS — Wills Eye Hospital —
 E. A. SHUNWAY and H. M. LANGDON — Children's Hospital —
 WENDELL REIMER — Polyclinic Hospital —
 L. PETER — Polyclinic Hospital — 3
 WILLIAM T. SPOONMAKER — German Hospital —
 CHARLES J. JONES — St. Joseph's Hospital — 3
 G. OZAM KING — Episcopal Hospital —
 LOUIS LOVE — St. Mary's Hospital — 2.
 E. D. FUNK — Jefferson Hospital — 2.
 AARON BRAV — Jewish Hospital — 3.

Saturday

E. D. FUNK — Jefferson Hospital —
 WILLIAM T. SPOONMAKER — Pennsylvania Hospital —
 GEORGE S. CRAMPTON — Pennsylvania Hospital — 2.
 P. N. K. SCHWENK — Wills Eye Hospital — 30
 WILLIAM ZENTMAYER — Wills Eye Hospital —
 H. G. GOLDREING — Episcopal Hospital —
 AARON BRAV — Leabson Hospital — 2.
 WILLIAM CAMPBELL POSEY — Wills Eye Hospital —

SURGERY OF THE EAR, NOSE, AND THROAT

Monday

CHARLES P. GRAYSON — University Hospital —
 R. SHILLER — Medico-Chirurgical Hospital — 2.
 L. JONES — Philadelphia General Hospital —
 MARGARET BUTLER — Women's Hospital — 2.
 CUTTES EVES — Episcopal Hospital —
 CARLE LEE FELT — Stetson Hospital —

Tuesday

F. R. PACKARD — Pennsylvania Hospital —
 D. B. KYLE — Jefferson Hospital —
 RALPH BUTLER and JAMES A. BARRETT — German Hospital — 30.
 I. G. SEALLCROSS and H. S. WEAVER — Habesmann Hospital — 30.

R SKILLERN — Medico-Chirurgical Hospital — 2
 FRED W SMITH and OSCAR SEELEY — Hahnemann Hospital — 2 30
 CHARLES C BIEDERT — Episcopal Hospital — 2
 LAURA E. HUNT — Woman's Hospital — 2
 WALTER ROBERTS — Methodist Episcopal Hospital — 3

Wednesday

WALTER ROBERTS — Polyclinic Hospital — 2
 RALPH BUTLER — Polyclinic Hospital — 3
 R. SKILLERN — Medico-Chirurgical Hospital — 2
 CARLE LEE FELT — Nelson Hospital — 2
 I G. SHALLCROSS and H. S. WEAVER — Hahnemann Hospital — 2 30
 FRED W SMITH and OSCAR SEELEY — Hahnemann Hospital — 30
 CURTIS EVES — Episcopal Hospital — 3
 HENRY C OTT — Oncologic Hospital — 2

Thursday

I G SHALLCROSS and H. S. WEAVER — Hahnemann Hospital — 2 30.

GEORGE M COATES — Polyclinic Hospital — 1
 FRED W SMITH and OSCAR SEELEY — Hahnemann Hospital — 2 30
 CHARLES C BIEDERT — Episcopal Hospital — 2
 WALTER ROBERTS — Methodist Episcopal Hospital — 3

Friday

SETH MACLURE SMITH — Jefferson Hospital — 2 30
 GEORGE M COATES — Pennsylvania Hospital — 1
 I G SHALLCROSS and H S WEAVER — Hahnemann Hospital — 2 30
 FRED W SMITH and OSCAR SEELEY — Hahnemann Hospital — 2 30
 GILBERT J. Pallen — Hahnemann Hospital
 CHARLES C BIEDERT — Episcopal Hospital — 2
 MARGARET WARLOW — Woman's Hospital — 2

Days to be announced

ARTHUR WATSON — Polyclinic Hospital.
 G HUDSON MAKUEN — Polyclinic Hospital.
 ALEXANDER RANDALL — University Hospital.
 CHARLES P GRAYSON — Medico-Chirurgical Hospital

PRELIMINARY PROGRAM OF EVENING SESSIONS

GENERAL SURGICAL DIVISION—In the Ball Room of the Bellevue-Stratford at 8 p m

Presidential Meeting Monday October 2

Address of Welcome ROBERT C LECONTE M D Philadelphia, Chairman of Committee on Arrangements.
 CHARLES H MAYO M D Rochester Minn. Address of returning president
 Inauguration of President FRED BATES LUND M D Boston and Vice Presidents JASPER HALPENNY M D Winnipeg and S M D CLARK M D New Orleans.
 Presidential address by FRED BATES LUND M D Boston The Indications of Cholecystectomy
 J M T FINNEY M D Baltimore Drainage of the Gall Bladder
 CHARLES H MAYO M D Rochester Minn Cholecystostomy vs. Cholecystectomy
 Discussion J C DACOSTA M D Philadelphia, and JOHN B DEEVER M D Philadelphia.

Tuesday October 4

DEAN LE TO M D Chicago Fat and Fascia Transplantation.
 Discussion FRANCIS T STEWART M D Philadelphia.
 C A PORTER M D Boston Surgery of the Peripheral Nerves.
 Discussion CHARLES H FRAZIER, M D Philadelphia and JOHN H GIBBO M D Philadelphia.

Wednesday October 25

J BENTLEY SQUIER M D New York City Kidney Surgery
 WILLIAM F BRAASCH M D Rochester Minn Recent Methods in Kidney Diagnosis.
 BRANFORD LEWIS M D St. Louis Diagnosis of Ureter Diseases with Their Surgery
 J T GERAGHTY M D Baltimore Diseases of the Bladder
 EDWIN BEER, M D New York City Treatment of Neoplasms by the High Frequency Current or Fulguration.
 Discussion EDWARD MARTLE M D Philadelphia.

Thursday October 26

THOMAS S. CULLEN M.B. Baltimore Methods of Draining Where Pelvic Infections Exist.

J. WHITRIDGE WILLIAMS, M.D. Baltimore The Abuse of Cesarean Section.

Discussion EDWARD P. DAVIS, M.D. Philadelphia.

GEORGE G. WARD JR. M.D. New York City Treatment of Inaccessible Vesico-vaginal Fistulae

Discussion JOHN G. CLARK, M.D. Philadelphia.

C. JEFF MILLER, M.D. New Orleans Surgical Treatment of Puerperal Pyemia.

Discussion BARTON C. HIRST, M.D. Philadelphia.

THOMAS J. WATKINS M.D., Chicago Cystocele and Prolapse

Discussion BROOKS M. AMSPACHER, M.D. Philadelphia.

Friday October 27

WILLY MEYER, M.D. New York City Cancer of the Breast.

WILLIAM J. MAYO M.D. Rochester Minn. Cancer of the Stomach

Discussion FREDERICK W. FARHAM, M.D. New Orleans.

EDITORIAL ANNOUNCEMENT

From time to time in the history of clinical medicine certain questions come up for intensive discussion appear to be settled temporarily and subside into quiescence only to reappear later as a subject again for forensic debate or laboratory research. Such a theme is that which has recently added considerably to the literature of neurology and gynecology. The relation between gynecological and neurological conditions has been recognized since the earliest days of medical knowledge. It has aroused the keenest discussion at various periods during past generations. Following the claims of Bossi a few years ago fresh interest in this subject was aroused. Today the close study given the ductless glands appears to reveal a closer relationship and to explain this relationship in some degree. It is, therefore timely that a critical review of this abundant literature should be offered to our readers and the INTERNATIONAL ABSTRACT OF SURGERY takes pleasure in announcing that Dr. Richard R. Smith has prepared such a paper to appear in the July issue.

Other collective reviews to be published during the next few months are

INTERNATIONAL ABSTRACT OF SURGERY

JULY 1916

COLLECTIVE REVIEW

THE VERMIFORM APPENDIX

A RÉSUMÉ OF THE LITERATURE

By W. FRANK FOWLER, M.D. ROCHESTER, NEW YORK

THE literature pertaining to the appendix has been extremely illuminating and in many instances conclusive during the past year. It is regrettable that a paper of this character cannot include all the excellent articles which were read in its preparation. The writer considers this compilation amply justified by the statistics of Murphy herein quoted.

ANATOMY

Recent embryologic studies of folds, bands and kinks have again demonstrated that various malpositions of the appendix are dependent upon partial or non rotation of the gut. Schrup (1) reports a case of this character which presented the usual symptoms of appendicitis and cystic ovaries. At operation the cystic ovaries were found in the ovarian region but there was no appendix caecum or ascending colon in the normal position. The jejunum occupied the right half of the abdomen. The caecum was located behind the sigmoid. The appendix was long and congested. There were no adhesions. The mesocolon was apparently attached at the left side of the spinal column. The stomach, heart and liver were in normal positions. A review of the literature convinces Schrup that complete transposition of the viscera is more common than the type which he reports. The pre-operative location of the heart on the right side would suggest the diagnosis in complete transposition. In childhood non-rotation of the colon accounts for unusual appendix positions.

Corner (2) says: Clinically it is frequent to find in children that the caecum and appendix have not reached the iliac fossa, but have been delayed in their descent or become situated in the umbilical region. It is unusual for the left side of the abdomen or the pelvis to be reached. Appendicitis in the young is commonly atypical and it is necessary to rely on the generality that acute abdominal disease in children is probably appendicitis. Other causes of malposition of the appendix in the adult are an abnormally long mesocolon and an unusually long appendix which may reach to the left side.

Palamountain (3) reports a case of another type. His patient was a married woman, aged 18, a nullipara who had had irregular menstruation for the past year. She was awakened by a sudden severe colicky pain in the midabdomen which continued all night and was accompanied by vomiting. The pain was localized in the left iliac region and continued all the next day with occasional vomiting. Castor oil and hot applications did not relieve the pain. The next day she was driven to town. Examination revealed a medium sized woman in severe pain. She leaned to the left side and kept the left thigh flexed. Menstruation had been delayed two days. Her temperature was 99.5, pulse 120. The abdomen was tympanitic and extremely tender over the left side. Percussion was almost unbearable. Muscle spasm was pronounced. There was constant pain over the left lower abdomen. The uterus was slightly enlarged and softened. The

cervi was soft. There was some pain in the left adnexal region, and there was a suspicion of a mass in the left side. A tentative diagnosis of tubal pregnancy was made. Operation was refused until the next day when pain and fever had increased. Operation was performed fifty-eight hours after the onset. It was found that the sigmoid was on the right side the ascending colon and ileum and a gangrenous appendix were on the left side. Peritonitis was present. Later examination located the liver on the left side and the heart on the right, a complete visceral transposition. No pregnancy existed. Death occurred in fifteen days from peritonitis.

Wade (4) describes some very unusual necropsy findings. The subject, a colored infant 6 months old died of pneumonia. The appendix, 2.5 cm. long, was found to be congenitally implanted in the inguinal canal. There was no evidence of appendicitis, nor of hernia. It was evident that the testicle, in its descent had carried the appendix with it. The tip of the latter was close above the testicle. The cecum was normally located.

PHYSIOLOGY

A meager knowledge of appendiceal physiology has been augmented by Heile (5) who states that his studies of the function of the appendix show that the musculature of the appendiceal region and of the appendix itself act together to insure effectual peristalsis. The walls of the appendix secrete tryptic and amylolytic ferments. There is also an internal secretion of hormones which stimulates peristalsis when injected into rabbits.

The investigations of Waller and Cole (6) which included the fluoroscopic examination of 27 children convince them that the appendix is a specialized part of the caecum with a definite peristaltic and sphincter action that fecal material normally retained in the appendix from one period of digestion to another, provides bacteria for colonic digestion. In brief that the appendix is a physiological culture tube. Incidentally the frequent occurrence of appendicular involvement revealed by examination of healthy children was surprising. Waller and Cole believe that appendicitis is essentially a lesion of early life.

Gunn and Whitelocke (7) learned from experiments that the removed appendix ceases contracting when placed in ordinary Locke solution, but when placed in oxygenated Locke's solution at body temperature the contractions recur. In appendices removed at operation there are typically present larger contractions with (usually) superimposed smaller contrac-

tions. A removed rabbit's appendix showed similar contractions, very much like those of the appendix *in situ*. They conclude that the contractions of the removed human appendix approximate those of the human appendix *in situ*. The nerve supply of the appendix is splanchnic and pelvic visceral. Appendices removed from children under ten years of age possessed the greatest contractions. A severely inflamed appendix may still show spontaneous movements of not definitely aberrant type.

ETIOLOGY OF APPENDICITIS

The most noteworthy contribution to the etiological investigation of appendicitis is the conclusion of Rosenow (8) that this disease in the absence of foreign body is usually caused by streptococci that these bacteria are located in some distant focus of infection that they simultaneously acquire an elective affinity for the appendix and entrance into the blood stream and are then carried to the appendix. The location and removal of foci of infection is an important measure of appendicitis prophylaxis. The co-existence of appendicitis and throat affections is thus explained. The danger in appendicitis lies in the fact that the anatomy of the appendix favors strangulation and the growth of facultative and strict anaerobes. In a more recent paper (9) on the elective localization of streptococci Rosenow states that 4 strains from appendicitis produced lesions in the appendix in 68 per cent of the 68 rabbits injected which is a marked contrast to an average of 5 per cent of lesions in the appendix in the animals injected with strains isolated from sources other than appendicitis. The localizations of the strains from appendicitis, ulcer of the stomach and cholecystitis as isolated after animal passage resemble one another very closely in cultural and other respects. Those from appendicitis are the least virulent, those from ulcer occupy a middle position and those from cholecystitis are the most virulent. The virulence seems to be one of the factors that determines their place of survival after intravenous injection.

Anderson (10) notes the relationship between appendicitis and tonsillitis. He states that the tonsil is well recognized as a port of entry of many systemic infections, and reports three cases of acute tonsillitis, with apparent subevidence of throat trouble soon followed by indefinite abdominal symptoms. In each instance a gangrenous appendix was found at operation. He summarizes as follows: (1) It is important to bear in mind the liability of appendicitis follow-

ing acute tonsillitis. (2) The appendicular involvement may be only part of a generalized infection; hence the gravity of such cases is out of proportion to the local symptom. (3) Such cases tend to become atypical in their clinical course and after smoldering suddenly develop fulminating symptoms. (4) Chronic tonsillar infections should be kept in view as the possible cause of similar infections of the appendix. (5) At least some degree of local tenderness and rigidity is almost always to be elicited on careful examination of the abdomen in the right iliac region in appendicitis; though in rare cases these signs may be absent.

The investigation of Savini¹¹ have convinced him that minute traumatic lesions of the appendix mucosa are very frequent. They are due to the presence of particles of carbon and iron. If these microscopic ulcer become infected necrotic appendicitis results. It remains aseptically the condition found at operation depends upon the stage of connective tissue repair. All stages of repair may be represented in different portions of the same appendix. He considers the irritation of the lumen to be an variable pathological.

Hughes¹² believes that the initial cause of appendicitis is mechanical a rotation of the appendix about its mesentery and the degree of rotation determining the extent of the attack. This movement is made possible by a movable loaded caecum, a loss of tone in the abdominal muscles. He affirms that a proper amount of exercise would decrease appendicitis.

Battle¹³ reports two cases in which the mucous membrane of removed appendices was deeply pigmented a brownish black. The discoloration was confined to the mucous membrane and evidently extended into the caecum. He had previously reported four similar cases. The patients were all women all of whom had suffered from chronic constipation and had had attacks of appendicitis. The deposit proved on analysis to be iron. Only one patient had taken iron. Battle believes that the rollers which grind the wheat for flour are the source. He found unusual traces of iron in flour but it could not be separated from the flour by a magnet. He concludes that iron particles may be an etiological factor in appendicitis. The sharp bite cause traumatic ulceration of the mucous membrane.

Suzuki¹⁴ made microscopical examination of 108 appendices removed at operation. He concludes that the ova may be found in the lumen mucosa or submucosa of the appendix without producing symptom or anat-

omalous changes. The presence of ova in appendicitis is usually accidental. A true inflammation is provoked when many parasites penetrate the wall of the appendix and the abraded tissue becomes infected in the lumen. It is extremely rare. (4) The source may cause a non-inflammatory painful morbid condition in the appendix accompanied by traumatic destruction of the tissue and hemorrhage a pseudo-appendicitis. Some defects of the appendix wall are art fact but are usually a cleft formed by the parasite.

Sherlock¹⁵ reports three cases of traumatic appendicitis. Case 1 A young man physician received a hard blow in the right side of the abdomen by the pillow handle. Severe pain followed. He ran a typical course of appendicitis and died on the ninth day having received perforation. The autopsy showed peritonitis and a perforated appendix with a contraction in the perforation. There was no history of previous attack. But necropsy revealed evidence of previous pathology. Case 2 A traveling salesman by the derailment of a car was thrown against the back of the seat in front of him. The severe initial pain soon disappeared but returned a few hours later with typical symptom of appendicitis. Operation revealed a perforated gangrenous appendix. There was a history of two preceding attacks. Case 3 A boy aged 12 years was struck in the abdomen by his brother's elbow. He immediately complained of severe abdominal pain which continued with vomiting and the ordinary symptom. A physician was called on the third day. Immediate operation revealed peritonitis a perforated appendix with gangrenous mucous membrane and a calculus. Sherrick¹⁶ quotes the conclusions of Deaver as follows: (1) From personal experience and a study of the literature trauma is never the direct exciting cause in a normal appendix. Acute appendicitis can follow a severe blow upon the abdomen or severe muscular strain but the appendix will present evidence of pre-existing pathology. Acute traumatic appendicitis is most frequent in males due to their more reactive life occurring between the age of 10 and 14. In an appendix previously diseased the liability to an acute attack following injury depends upon the degree of injury and the pathogenicity in the appendix at the time of injury.

The mortality is high due to late diagnosis rapid gangrene and perforation and late operation. (6) When the history suggests traumatic origin a record should be made of the cause of the injury and also of the operative findings.

PATHOLOGY

Stickney (17) reports the case of a woman, aged 39, who had had symptoms of chronic appendicitis for a year. At operation a small clubbed appendix was removed. The clubbed tip was a circumscribed solid tumor without lumen. Examination revealed 5 small myomata in this area. Out of 647 reported cases of tumor of the appendix, only 3 were myomata.

Primary carcinoma of the appendix, although formerly considered an extremely rare pathology, is stated by Meyer (18) to occur in 0.5 per cent of removed appendices. Meyer reports three cases. The diagnosis was made microscopically. Pre-operative diagnosis is impossible, and diagnosis at operation unusual. The condition is histologically malignant, but clinically benign. Nevertheless clinically malignant cases do occur. The tumor occupies the appendix tip with obliteration of the lumen. The growth was noted to be of a yellowish brown color in one case. Ras-leur (19) reports two cases. In the first the yellow color was noted on section and the diagnosis made microscopically. The same color observed on section in the second case, led to macroscopical diagnosis, which was later confirmed by the microscope.

Pseudomucinous cyst is a truly rare lesion. Phemister (20) states that it results from the slow accumulation of an altered secretion of the appendix produced by a mild inflammatory process. Most of the cases have occurred between the ages of 35 and 50. The fluid which accumulates during an acute attack of appendicitis varies from serous to purulent or ichorous. The accumulation either disappears rapidly with the subsidence of the acute inflammation or escapes into the peritoneal cavity through a perforation. Persistence of this fluid with chronic cyst formation is rare. However cases are reported of stenosis of the proximal portion, with pus accumulation in the part beyond leading to the formation of chronic empyema of the appendix. Chronic hydrops following milder attacks in which the appendix is filled with a simple serous exudate is also very rare, because the mucous membrane is preserved in such cases, and its secretion changes the character of the contents so that pseudomucinous cysts usually result. The cause of the stenosis and retention of secretion is uncertain. It is probable that inflammation and involution are associated in varying degrees in the causation. Often there is no history of preceding attacks of appendicitis, and if so they have been mild. The lumen of the

appendix is filled with a transparent, gelatinous material which is usually quite thick. It contains no faeces and usually no bacteria. There are few clinical symptoms and development is slow and painless. Sometimes the first symptom is the appearance of a mass in the right lower quadrant of the abdomen. Phemister reports a case in which the removed appendix was 21 cm. in length and 21 cm. in its greatest circumference. It was filled with a thick, gelatinous material. Portions of the wall were thickened and some of these areas suggested calcified plaques.

Phemister states that pseudomycoma peritonei results from rupture of the cyst. Frankel in 1901 described the first case arising from a perforated colloid cyst of the appendix. About 30 cases have been reported since. Perforation is usually symptomless and the pseudomucinous material is disseminated on the peritoneal surface in various sized masses. There are usually no symptoms subsequent to rupture as the contents are sterile. This condition is cured by removal of the cystic appendix as the source of the material is removed and the remaining portion is absorbed. In a case reported by Ogilvie (21) the patient complained of something solid "tapping him on the inside at the appendiceal region while he followed his daily work. A hard irregular mass was palpable over McBurney's point. A roentgenogram revealed a shadow which might be a calcified cyst of the appendix or a ureteral calculus. At operation a calcified appendix was removed. Examination revealed a pseudomycomatous cyst whose walls were almost entirely calcified. The base of the appendix contained mucoid material while the distal portion was filled with pus.

Pfiffner (22) in a paper on appendicular obliteration states that chronic appendicitis pathologically includes low grade inflammation and end-results of such an inflammation. The latter is evidenced by cicatrices, strictures, kinks, and by destruction and replacement of mucosa by fibrous tissue, with obliteration of the lumen. The latter is not a physiological process. In 100 surgically removed appendices the occurrence of obliteration was most frequent during the age of active inflammation (20 to 30 years) and was not dependent upon the advanced age of the patient. This contention is borne out by a case recently operated upon by the writer. The patient was 70 years of age and the appendiceal mucosa was gangrenous with obliteration of the lumen only at the tip. Pfiffner classifies three types of symptoms due to an obliterated appendix: (1) reflex, due to irritation of the nervous

mechanism of the appendix (2) local due to mesenteric and peritoneal contractions and inflammatory bands and adhesions affecting the appendix or contiguous bowel (3) consecutive symptoms general and local consequent upon disturbed function of the iliocecal region. Simple appendectomy avails for relief symptoms but in local and consecutive symptom only in so far as the operation permanently relieves the symptom producing contractions, sclerosis or adhesions. The determination of these latter conditions and the appropriate treatment therefore awaits further observations and experience.

Another type of obliteration is described by Bonn (12) who reports seven cases of tiliform appendices. A tiliform appendix so named and described by Eastman (14) is a slender white cord usually covered entirely or in part by a pericolic membrane. If only partially covered the unconstricted portion may be of normal size. The end may be free or attached to the parietal peritoneum. The constricted part is without lumen. A tiliform appendix may be mistaken for an adhesion or the appendix may be considered congenitally absent or pathologically destroyed. Bonn believes that two processes are associated in the production of the tiliform appendix, namely, a chronic inflammation and an involution due to constriction by the accompanying pericolic membrane.

Judd (25) reports a case of auto-amputation of the appendix a term used by Murphy (10). Judd's case was a young man with indefinite symptoms of appendicitis. During a kidney operation the appendix was brought into the incision. It was connected with the cecum only by a fine adhesion. Pinching at this point with the fingers entirely separated the appendix from the cecum. There was no opening into the cecum. The proximal end was also closed. The appendix was 7 cm long, not dilated and contained a small amount of mucoid material. It showed the lesions of a chronic interstitial inflammation.

DIAGNOSIS

The diagnostic value of rigidity of the right rectus has been so greatly emphasized according to Randall (1) that many cases of appendicitis have been neglected in the absence of this sign. He states that ordinarily rigidity of the right rectus is a reliable guide, but in some cases rigidity of the right external oblique is present in its stead. These cases are mild, many patients are about and attending to business and a high polymuclear count is the only indication of a

serious condition. In over 60 cases seen the patient was by Randall with rigidity of the right external oblique and not of the right rectus, the appendix was retrocecal and retroileal.

Ten Horn (18) reports that traction upon the right spermatic cord produces pain in appendicitis. This he noted in about 10 cases. The cord is grasped above the testis and gently pulled without making pressure on the testis. He believes the pain to be due to irritation of the peritoneum about the internal ring. He found the value of the cremasteric reflex sign.

Ruthkevitch (19) believes that chronic appendicitis is frequently diagnosed as some functional gastric or intestinal disorder. It is very common. Many patients given history of previous attack of characteristic pain. Examination tenderness at McBurney's point and temperature are either negative. Ruthkevitch could not elicit Rovsing's sign and leukocytes were present only once. He concludes that there are no diagnostic signs of chronic appendicitis. Palpation is the best guide. He palpated the appendix in 60 per cent of cases and pain was produced in 48 per cent. The palpation also caused pain in the upper abdomen at the same time in many cases. His method of palpation is as follows: The flexed fingers of the right hand are pressed down between the external wall of the cecum and the abdominal wall. The fingers are then extended and an endeavor made to deflect the cecum toward the median line. This manipulation invariably produces pain in chronic appendicitis.

Blachoff (20) distends the previously emptied bowel with air through a rectal tube. By this means pain over McBurney's point is elicited in the appendix diseased (Bartoloni's sign). Pain over the appendix as ordinarily observed should not be considered diagnostic of appendicitis as it is caused by other conditions.

Lanz (31) states that frequent and painful urination in children may be an early sign of appendicitis. When the finger is introduced into the right inguinal canal the muscles contract about it if the appendix is inflamed. The cord is painful and tender. Contrary to Ten Horn, Lanz believes that the cremasteric reflex is weak or absent in acute appendicitis.

Sutton (32) reports a case of appendicitis with unusual features in a young unmarried woman. At 5 a.m. he found the patient suffering from intermittent colicky abdominal pain, abdomen tympanic, temperature and pulse normal. No abdominal tenderness. He gave soap-suds enema, liquid diet and castor oil. Diagnosis, acute intestinal indigestion. At 4 p.m. the tempera-

appendicitis by palpation and X ray. This was confirmed by operation and the patient has regained her normal health. Kenebeck says, The irritation or traction spasm originates at some particular attachment of the appendix to a branch of the mesenteric plexus and reaches the musculature of the stomach by way of the mesenteric and celiac plexus as follows: (1) hepatic plexus and plexus gastroduodenalis to the pylorus; (2) plexus gastro-epiploica dextra to the pylorus and lesser curvature; (3) plexus gastroduodenalis to the fundus and region of greater curvature. Afferent impulses in general pass from an inflamed appendix to the mesenteric ganglia, suprarenal ganglia, vagus to medulla and thence independent of the spinal centers.

Aaron (40) previously had noted that pressure over the appendix caused epigastric pain. Recently while examining a case of chronic appendicitis with the fluoroscope he induced a pylorospasm by pressure over the appendix and coincident epigastric distress of which the patient had frequently complained. Aaron believes this reflex pain is caused by pylorospasm and ventures the opinion that the gastric symptoms of appendicitis are also due to this spasm.

Aynesworth (41) states that the average incidence of appendicitis in children up to 15 years of age is 15 per cent. The large number of such cases are due to late diagnosis and rapid development. Cases have been reported as early as the fifth week. Failure to make a diagnosis due to oversight rather than to symptomatology. Unfortunately other acute mild abdominal conditions are common leading to late diagnosis, and children do not readily localize painful areas. The history is scanty. Nevertheless Aynesworth believes that the diagnosis can be made fairly early. Abdominal pain is usually the first symptom. Children with even slight peritoneal involvement protect the abdomen very carefully. The appendix may be anywhere in the abdomen. When it lies in the pelvis there may be no abdominal rigidity and tenderness only deep in the pelvis. In the presence of bladder irritation or doubt of diagnosis a rectal examination should be made. Pain, vomiting, tenderness, rigidity in any part of the abdomen and fever strongly indicate appendicitis. Gastroenteric affections must be excluded. Examination of the lungs should be made in children whenever an acute abdominal condition is presented.

Fleischner (42) reports the following case. A child 8 years of age became acutely ill with

fever, vomiting and pain in the right side of the abdomen. Twelve hours after the onset there was a leucocytosis of 30,000. A tentative diagnosis of appendicitis was made. Upon examination light percussion of the chest revealed relative dullness over the right lower lobe of the lung and on auscultation the breathing was slightly diminished. There was no distention of the abdomen and abdominal respiration was normal. Considerable pain was complained over McBurney point and extending upward but neither tenderness nor rigidity was commensurate with the pain. Operation was postponed for twelve hours. At this time pneumonic symptoms were more evident. In twenty-four hours there was no doubt of pneumonia and pain had disappeared.

Gage (43) states that pain, tenderness, and muscular spasm in the right iliac region occurring during typhoid and render differentiation from appendicitis difficult. The difficulties are increased by the fact that the appendix does share in the intestinal lesions of typhoid as instances by case reports of ruptured typhoid ulcerations of the appendix.

Gage divides the appendicitis of typhoid into 3 classes: (1) appendicitis, an accidental accompaniment of typhoid or chronic condition become active; (2) typhoid ulceration of the appendix; (3) appendicitis occurring soon after typhoid as to be due probably to it. An unusual case of post typhoid appendicitis was reported by Stokes and Arncliffe (44). A young man who had had typhoid 10 years before developed acute appendicitis. The appendix was gangrenous and the bacillus Eberth was cultured from it. The Widal reaction was positive. Was he a carrier? Several cases have been reported of accidental complication of appendicitis without evidences of typhoid involvement but due to mild infection with typhoid bacillus.

Gage reports a case in which acute right iliac pain, rigid rectum and vomiting developed when the typhoid temperature had been normal for five days. The leucocyte count rose rapidly to 18,000. Laparotomy for probable perforation revealed an unruptured gangrenous appendix lying in a walled off abscess. The pathologist reported typhoid ulceration and the presence of typhoid and colon bacilli as well as streptococci. Gage believes that careful examination of removed appendices for so-called accidental inflammation would reveal the presence of typhoid lesions in many cases. He emphasizes the importance of a rising leucocyte count.

Winlow (45) reports 4 cases which were operated on.

Wale report the case of a girl 22 years of age who was seized with a violent attack of pulmonary tracheitis while at the hospital for the treatment of her nervousness.

but soon recovered. Nausea and vomiting were followed by relief. There was slight tenderness in the lower right quadrant. At operation, upon delivery of the appendix, the partially anesthetized patient strained causing the apparently normal appendix to inflate alarmingly. Pressure was required to accomplish deflation. The appendix contained a No. 6 hard shot. There were no inflammatory changes. Waller believes that this case accounts for hitherto puzzling attacks of acute colic in which the appendix was not pathological but contained small concretions or foreign bodies, these concretions or bodies acting as a ball valve preventing ready deflation and producing symptoms of colic.

Strauss (55) reports five cases of extraperitoneal appendicitis which he classifies under three heads: (1) Those presenting a straightforward picture of appendicitis. In these cases the appendix cannot be found until the peritoneum is incised near the cecum and the latter lifted up. (2) Those simulating a perinephritic abscess. This type is characterized by pain, tenderness, and swelling in the right lumbar region. Through the lumbar drainage incision it may be possible to remove the appendix without entering the peritoneum. (3) If the appendix is not removed a persistent fecal fistula may result. Fœtid pus obtained from a lumbar abscess is probably due to disease of an extraperitoneal appendix. Careful search should be made before deciding that the appendix is absent or has sloughed away.

Lichty (56) who reports about 700 cases of appendicitis from the view point of the internist, is impressed with the fact that many cases of supposedly chronic appendicitis are operated upon without relief of symptoms. He summarizes as follows: (1) A close co-operation of physician and surgeon is necessary to obtain the best results. (2) Since only 8 patients out of about 700 under all conditions and circumstances, died the disease need not be considered with such alarm. (Lichty refers to cases hurriedly diagnosed and operated upon for chronic appendicitis in which there may be no pathology in the appendix.) (3) An early operation during the first acute attack is not only safest but will likely prevent a life of more or less chronic invalidism. (4) A careful routine study of the leucocytes in acute appendicitis is of diagnostic value. (5) A routine study of the gastric secretion in chronic appendicitis yields valuable information (hyperchlorhydria). (6) The end-results in cases of chronic appendicitis are often unsatisfactory and cannot be definitely foretold.

TREATMENT

Guthrie (57) reports the use of the serum and vaccine of colon bacillus in 22 cases of appendicitis. All recovered without operation. There was one recurrence here too little of the serum was used and no vaccine. The relief from pain was striking. Serum should be used before pain becomes localized. He gives 50 ccm. of the serum and a few days later 100,000,000 colon bacillus vaccine to prevent recurrence. The fixation of complement test should be made and if some other organism is the determining cause a corresponding serum or vaccine is indicated.

Syms (58) reports a mortality of 100 per cent in a series of peritonitis cases of appendiceal origin in 1904. The mortality of a series in 1912 was 16 per cent. Improved operative methods have decreased the death-rate. Syms agrees with Murphy that peritoneal peritonitis tends to be localized or general from the very start, depending upon the kind of bacterium responsible and the patient's resistive power. He disagrees with Stanton (59) in his conclusion that dissemination of peritoneal infection is largely a matter of peristalsis and that the quiet afforded by withholding food and water by mouth will prevent its spread. Syms believes in immediate operation at any stage of appendicitis. If infection is present a rapid, simple operation with drainage is indicated the drains being placed between the intestines and the parietal peritoneum. The after treatment consists in washing the stomach if there is nausea, vomiting or extreme sepsis and withholding food and water per mouth for 4 to 48 hours, keeping the patient in the Fowler position, use of the Murphy drip clear by the lower bowel by enemata to relieve distention, no cathartics, few drugs, no opium stimulation if necessary. If the pulse or heart is weak the Fowler position should not be used. Post-operative ileus is due to spreading peritonitis, septic infection, excessive manipulation at the time of operation, faulty placing of drains, failure to empty the lower bowel before distention, and the use of morphine or opium.

The principles of the Ochsner method as outlined by Hicks (60) are as follows: The medical treatment, if it can be called such, consists in the prohibition of food, physac and generally of water, lavage at times, rest in bed, mild heat applied locally. All cases seen in the first 24 hours are operated upon at once if willing, a few are operated upon on the third day but cases from the fourth to ninth days, especially if

very ill are treated medically until a safer time for operation.

Deaver and Pfeiffer (61) agree with Ochsner in their statement that early operation in appendicular peritonitis is the rule but is of no benefit and may be harmful in cases of more than 40 hours duration with signs of diffuse peritonitis and marked systemic toxemia. Removal of the appendix is of no avail as that organ is buried in a mass of omentum and coils of intestines and is incapable of adding to the infection. Spreading peritonitis cannot be checked by surgical means. The best treatment is supplying rest to the alimentary tract by withholding everything by mouth. The Fowler position and enterocolysis are important. When the outlying inflammation subsides and localizes about the appendix the latter may be removed or the pus which is about it. The after treatment consists in the sitting posture, enterocolysis, nothing by mouth and careful nursing.

ANÆSTHETIC

In a consideration of choice of an anæsthetic Bevan (62) states that drop ether should be chosen today as the standard general anæsthetic when a prolonged anæsthesia is desired with relaxation and unconsciousness. Gas should be chosen in short anæsthesias and in special cases such as kidney insufficiency. Local infiltration anæsthesia may be used when the surgeon has the full co-operation of the patient and when the field of operation can be completely infiltrated and anesthetized by a safe amount of novocaine and epinephrin. He believes that nerve blocking should as a rule be confined to nerves which are exposed by a dissection done under local infiltration as in a herniotomy.

Harris (63) reports 34 appendectomies done under nerve blocking. The appendix is insensitive but novocaine must be injected at the base of the meso-appendix. The method is safe and free from the dangerous sequella of general anæsthesia. The psychic element has been overestimated. Dread of operation is based upon fear of pain which may be abolished by assurance that there will be none upon loss of consciousness which does not obtain with local anæsthesia and upon fear of the outcome. This fear may be mitigated somewhat by the fact that patients are apt to consider an operation which can be done with local anæsthesia as less severe than one requiring a general anæsthetic. Nerve blocking teaches the surgeon to employ gentle manipulations which tends to decrease shock.

Brun (64) says. The writer confesses that

after many attempts some of them dating back a long time he always returns to the same conclusion that is to perform operations on the appendix under general anæsthesia without local anæsthesia.

INCISION

Our views in regard to the most desirable incision for appendix removal have recently been modified. Brickner (65) states that the McBurney incision is satisfactory for a simple appendectomy but a presumably simple appendectomy may resolve itself into a more extensive operation requiring liberal exposure. The incision is not suitable for exploration of the upper abdomen so often indicated nor does it lend itself to enlargement. Its routine use would lead to otherwise avoidable technical difficulties and conditions might be overlooked which would be observable through the right rectus incision.

Harrigan (66) describes a modified McBurney incision for the treatment of appendicitis and pelvic disease as follows: 1) After removal of the appendix the peritoneum and internal oblique and transversalis muscles are sutured. (2) The skin incision is extended downward and inward toward the median line. (3) The aponeurosis of the external oblique is divided to the point where it fuses strongly with the anterior rectus sheath. (4) The anterior rectus sheath is incised parallel to the line of fusion of the external oblique muscle leaving a sufficient margin internally to suture. (5) The rectus muscle is freed, displaced and retracted outward. (6) The peritoneum is incised.

Rockey (67) describes the transverse incision as follows. The skin incision 2 to 2½ inches long is made directly transverse with its center at or near McBurney's point. The outer part of the rectus sheath is incised dividing the tendinous border and the aponeurosis of the muscles on a directly transverse line. The scalpel handle is inserted below and the finger above and the wound pulled wide apart without cutting any muscle fibers. The external oblique fibers are retracted at the outer angle and the rectus at the inner angle. The peritoneum is divided transversely. Definite pre-operative diagnosis is essential as this incision is not adapted to other pathological conditions. In interval cases and acute cases before rupture the operation is facilitated and firm union obtained. In pus cases it gives direct approach. Drainage is placed in the outer angle of the incision and the outer side of the cæcum. Rockey believes that liability to hernia is diminished.

OPERATIVE TECHNIQUE

Torek (68) has described a combined incision for appendectomy and right herniotomy. The skin incision usually employed in herniotomy is prolonged outward and the appendix is removed through a muscle splitting incision beyond the internal ring.

An interesting variation of operative technique is described by DeTarnowsky (69). He advocates the routine removal of the appendix through the internal inguinal ring during right herniotomy. His results have been satisfactory in over 50 cases. The cecum is distant only 4 to 6 cm from the internal ring and can be partially or totally delivered. If the ring admits two fingers or can be easily stretched to admit them he delivers the cecum with the index and middle fingers. A freely movable appendix may be delivered with the index finger alone. Gross pathology was evident in 30 per cent of the appendices thus removed. He does not advise this route in acute appendicitis.

Neill (70) describes Cullen's method of exposing a retrocecal and densely adherent appendix. The base of the appendix can usually be located. When this is accomplished blunt forceps are pushed through the meso-appendix at this point and a tape drawn through. Traction upon the ends of the tape brings up from three fourths to one inch more of the appendix. Another tape is inserted as before and this maneuver repeated until the appendix tip is delivered. Usually three tapes are sufficient. The meso-appendix is clamped off and the remainder of the operation carried out according to indications.

White (71) reports a case of appendicitis, drained with a rubber tube in which an active hemorrhage began four days after operation and continued twenty four hours although packing was tightly inserted about the tube. He believes that the hemorrhage was produced by erosion of the deep epigastric artery by the drainage tube. Fatal hemorrhage has occurred from this source. The artery is frequently exposed with its companion veins, in the incision. White applies two ligatures about one inch apart to these vessels in the lower angle of the incision. Free anastomosis insures adequate blood supply. He believes that ligation should be routine in this class of cases.

Petitt (72) describes a method of drainage through the McBurney incision. The drainage tubes lie close to the ilium at the outer end of the split in the internal oblique and transversalis. These muscles are then sutured to the tubes. A

slit is made in the external oblique close to the ilium and the tubes are drawn through. Finally they are brought out through a corresponding small skin incision close to the anterior superior spine. The drainage canal is thus placed between the cecum and the bony wall of the pelvis. Primary union of the operative incision is facilitated.

Benjamin (73) deprecates the practice of leaving the raw appendix stump uncovered as adhesions are invited. Nature must cover it over with tissue exudate.

Carter (74) describes his method of disposing of the appendix stump as follows. The appendix is clamped near the base and cut off. The suture is threaded on a round needle. The needle is inserted into the cecum about one-fourth inch from the stump and emerges about one-fourth inch beyond parallel with the base of the appendix. Repeating this maneuver twice more surrounds the stump with a triangular stitch. An assistant enters the stump into the bowel and the suture is tied. A few reinforcing Lembert sutures may be inserted.

The Mayo (75) appendixomy so beautifully demonstrated by the teretoculic of Kelly is probably the best known method. The writer expresses continued confidence in a procedure which he has previously described.

COMPLICATIONS

As a complication of appendicitis, Delatour (77) reports seven cases of pelvic abscess following the Fowler position. The patient does well for a time although there is persistent slight elevation of temperature. The incision has ceased to drain and the patient may be allowed to go home with a temperature slightly above normal. Others suddenly recover. Delatour believes that all these cases have undetected pelvic abscesses of comparatively slight virulence. Sudden recovery is due to rupture of the abscess into the rectum. In this series the abscess was disclosed by rectal examination. Treatment consisted in incision per rectum unless the abscess was located high up in which event it was aspirated.

Babler (78) believes that pyelophlebitis with multiple abscesses of the lung or liver is a more frequent complication of appendicitis than is realized. In a typical case the diagnosis rests on (1) the history showing that the appendix was the primary seat of trouble (2) the shifting of the symptoms from the appendix to the hepatic region (3) the progressive increase in the severity and character of the symptoms (4) the

repeated chills followed by high pulse rate and marked elevation of body temperature (1) the jaundice (2) the persistent pain in the hepatic region (3) the urinary and blood findings (4) the change of liver dullness (5) the picture of marked toxæmia and (6) the absence of the signs and manifestations of extensive peritonitis. Multiple abscess of the lung is indicated by repeated chill, septic temperature and persistent cough. The only hope of relief lies in locating and draining the abscesses. Haller reports three cases (1) were abscesses in the liver one of the lung. All were fatal.

Markoe (19) quotes Deaver as follows: "The earlier the operation for appendicitis during pregnancy the less the likelihood of infection of the right tube and ovaries and the less likelihood therefore the development of serious complications. I have never had abortion occur in pregnant women upon whom I have operated for acute appendicitis unless the right uterine appendages are involved in the disease and seldom then." Markoe believes that abortion in these cases is caused by undue handling of the uterus and incision. He reports two cases. Case 1. Age 23. 1 para. had had acute pain in the appendiceal region for some time. Examination revealed a five month pregnancy, there was acute pain a little above McBurney point and some rigidity of the right rectus. Incision was made at McBurney point. The appendix was not adherent to the ascending colon. The greatest care was taken that the uterus, fall pian tube and ovary were not injured or manipulated, they being held to one side with a pair of wet cotton forceps. The appendix was removed. The patient made an uneventful recovery and four months later was delivered at full term. Case 2. The patient was suffering several days with marked rigidity, temperature 101 F, a white cell count of 16,000 and polyuria. Immediate operation was advised and the advice accepted. A median incision was made from the umbilicus to the symphysis. The omentum extended down over the right tube and ovary, being firmly adherent to the uterus. The omentum was tied off, then the appendix which was embedded in this mass was tied off and the stump buried. This left a mass consisting of a piece of omentum, right tube, ovary and appendix attached to the uterus and right broad ligament. The right tube was very gently tied off and cut away and the adhesions which held the appendix, omentum and ovary were then removed from the uterus. Stal wound drainage was provided. The patient aborted with a 4.5

month fetus within twelve hours of operation. Otherwise her recovery was uneventful. Markoe states that the appendix is not drawn up into the abdominal cavity by pregnancy, but on the contrary may be brought up with difficulty into the incision.

Wallace (81) reports a case of ruptured appendix at full term pregnancy as follows: "The patient called him at night for supposed labor pains. He found her sitting up and complaining of severe pain low down on the right side. There was slight cervical dilatation. The head was not engaged. The next afternoon she was still in pain and had become continuously. Temperature 103.6 F, pulse 118. Vaginal examination revealed no increase in dilatation but sign of abscess in the appendiceal region. An ice cap was applied in the hope that peritonitis could be delayed until after delivery. The next day the temperature was 104 F, pulse 140. Appendectomy was performed and the abscess drained. The incision was closed with exceptional care about the drains in order to withstand the severe strain of labor. Closure was difficult and he believed would have been impossible had he not incised the fascia transversely. The next day, after one and one half hours of labor, a normal delivery was accomplished under anesthesia. Recovery was uneventful. The dilatation of McBurney point in the pregnant abdomen was noticeable. It is difficult to determine where to make the incision."

QUESTIONS

Bunts (82) reports an interesting sequelæ of appendectomy. The patient was a nurse who had had a clean appendectomy performed several years previously. She was free from discomfort for nearly a year after operation when she again complained of pain in the right side. The attacks were very severe. Examination revealed a somewhat enlarged ovary. At operation the right ovary was found slightly enlarged and cystic. At the site of the former purse-string suture on the cæcum was a white ring which formed the base of a conical projection of the bowel about one inch in length. Fearing the possibility of rupture of the thin-walled liver-uticulus and that distention it might cause volvulus Bunts invaginated the protrusion into the cæcum and secured it with a double purse-string suture. There has been no recurrence of pain. He has since found the same condition in two other cases, but in lesser degree. In all three cases the right ovary was abnormal and might have been counted for the pair of which they all

complained. He believes the condition to be not uncommon and that future observation will prove it to be responsible for recurring pain in the right side after appendectomy.

Case (83) states that a common cause of cecal stasis is adhesions, usually associated with disease of the appendix. Immediately following recovery from appendectomy there is usually considerable cecal stasis. Following the attempt to expel the barium enema, it is seen that the cecum has failed to contract, the peristaltic waves which evacuate the large bowel commencing at or above the ileocecal junction instead of at the tip of the cecum. Even several years after operation cecal stasis persists in many cases, a round residue of barium the size of a 25-cent piece remaining in the cecum after the colon is otherwise emptied of barium. This is especially likely to occur where the patient complains of a tenderness of the cecum. Sometimes this cecal stasis was present before the operation, but often exists after operation where it did not exist before. He believes that the rounded barium occurs at the site of the stump of the appendix and that it has some relation to the invaginating suture by which the stump is buried. This suggests the desirability of including the least possible amount of cecal muscularis in the suture.

In a series of 276 cases of intestinal obstruction reviewed by McGlannan (84) 63 were post-operative. Nearly 40 per cent of the post-operative obstructions and 10 per cent of all cases in this series followed drainage operations for appendicitis. This is a potent argument in favor of early operation at a time when no drainage is required. Had these patients been operated upon early all would have been spared a second operation as a result of which 9 died. Prompt operation in appendicitis and careful covering of surfaces in all abdominal operations will afford efficient prophylaxis against post-operative obstruction.

In a series of cases of acute intestinal obstruction reported by Deaver and Ross (85) 81 were due to post-operative adhesions. Fifty-one cases followed operations for appendicitis and 44 were drained at the original operation. 27 died.

PROGNOSIS

The prognostic value of post-operative leucocyte count is discussed by White (86). He states that a secondary peritoneal infection with good resistance shows an early and marked increase of leucocytes and will continue for some time. The leucocyte count is a safe guide as to conditions within the abdomen. In general

peritonitis a constant low or declining leucocytosis denotes a grave prognosis.

Elsner (87) believes that an unusual amount of urobilinogen in the urine during appendicitis indicates a destructive lesion of the appendix.

MORTALITY

Turner (88) states that the mortality of appendicitis should be less than 5 per cent. Early operation would decrease the death-rate to 1 or 2 per cent, or it might become practically nil. Appendicitis is not inherently dangerous. The result is a question of degree of peritonitis and the stage of the disease when operated upon. At present over 60 per cent of cases are operated upon when involvement is localized. Ten years ago conditions were reversed.

Kakela (89) believes that the majority of deaths from appendicitis are due to failure in making a diagnosis, the abdominal pain being assigned to other abdominal organs rather than the appendix. Early diagnosis should be easy if we remember the following train of symptoms: sudden generalized abdominal pain, gradually becoming localized nausea and vomiting, general abdominal sensitiveness, local rigidity, elevation of temperature, leucocytosis and rapid pulse.

Murphy (90) makes the startling statement that the mortality of appendicitis in the hospitals of the United States is 10 per cent. This death rate is due to procrastination. The early symptoms are usually diagnostic later they are obscure. Early symptoms are no guide to the probable outcome. Pain and temperature may be gone by the second day which may mean resolution or gangrene. A gangrenous appendix produces neither pain nor leucocytosis. The next symptoms are those of general peritonitis. The mortality in childhood is three or four times as high.

CONCLUSIONS

1. The incidence of primary carcinoma of the appendix suggests the advisability of routine appendectomy during laparotomy.

2. Infection of the appendix by bacteria carried through the blood stream from a distant focus is an established fact.

3. Typhoid fever and pneumonia in their early stages may be difficult to differentiate from acute appendicitis.

4. The chief symptoms of chronic appendicitis may be referred to the epigastrium.

5. Undue retention of barium in the appendix and tenderness of that organ elicited under visualized palpation are roentgen signs of great diagnostic value.

6 Appendicular bliteration an end result of inflammatory changes and is self-productive of symptoms

Excepting the frank case of a cecal appendix diagnosis uncertainty or coincident pathology demand ample incision hence the right rectus approach.

8 The mortality of appendicitis is too high. Early diagnosis and early operation are essential to low mortality.

ABSTRACTS OF CURRENT LITERATURE

GENERAL SURGERY

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE

Primrose A. The Physics of a Surgical Dressing with Special Reference to the Harmful Effect of Using Impermeable Material Over Septic Wounds. *B. M. J.* 1916, 1, 215

The author refers to an article by Sir Muroth Wright in which Wright advocates the use of sodium chlorid 5 per cent with sodium citric 0.5 per cent as a solution for moist dressings, these being covered by an impermeable ring. The author objects to the use of an impermeable ring over moist dressing, where drainage is desired. He cites experiments to show that capillary attraction is lessened or made nil when evaporation is a part of the dressing prevented. The experiments were carried out by using disks containing water, a gauze wick being saturated and placed therein with one end protruding. A crystal of an aniline dye was then placed in the wick. If the flask was uncovered the dye rose in the wick, whereas if an impermeable substance was placed over the flask the dye did not rise. This objection to Wright's recommendation says the author is especially tenable where the wound is an infected one where drainage is greatly to be desired. *111 SKINS*

Fisher H. E. Non-adhering Surgical Gauze. *J. Am. M. A.* 1916, 1, 439

Fisher has experimented with various materials in the dressing of open wounds. Absorbent cotton, chamois, skin and powders, he rejects as unsatisfactory. Cutta percha and silver foil if perforated gave fairly good results. Plain surgical gauze is satisfactory, except that it adheres to granulating wound is a disadvantage which is less troublesome if narrow mesh gauze is used. Medicated gauze he found to have no particular advantage over plain gauze.

He secured the best results from the use of gauze impregnated with paraffin in the following manner: Eight parts of paraffin mixed with two parts of white petrolatum and lanolin is boiled for ten minutes. Then dry sterilized gauze in strips is immersed for ten minutes in the mixture. The gauze is gradually removed and stretched and allowed to dry in a current of filtered air, which frees the apertures of excess paraffin. In use one layer or two is placed in direct contact with the wound or raw

surface. In ordinary surgical gauze fluid is placed above it. The gauze can be changed as frequently as desired. In the waxed gauze can be left on for a considerable period. The advantage is it is lifted off.

The author finds that this method of dressing has the following advantages: (1) It does not adhere to a granulating wound and can be left on for a considerable period. (2) It causes no pain or discomfort on application or removal. (3) The paraffin is not absorbent and the gauze does not become matted with secretions and debris. (4) It loosely conforms to the surface to which it is applied. (5) It allows a adequate drainage of the wound secretions through the meshes. (6) It is easily and quickly sterilized by immersion in absolute grain alcohol. (7) It is of particular value in the treatment of skin grafts.

ALBERT EHRHARDT

ASEPTIC AND ANTISEPTIC SURGERY

Fraser J. and Bates, H. J. The Surgical and Antiseptic Value of Hypochlorous Acid (Eusol). *B. M. J.* 1916, 1, 21

The method of preparation of eusol is as follows: In a quart bottle 27 gm. of dry bleaching powder are placed, 1 liter of water added to this and the mixture shaken. Then 27 gm. of boric acid are added and the bottle filled with water after standing for a few hours the mixture is filtered. The filtrate is eusol and contains about 0.5 per cent hypochlorous acid.

Gunshot or stab wounds packed with gauze soaked in eusol solution show beginning granulations within 36 hours. The objections made to the use of this solution are the pain it causes, the irritated and soiled condition of the surrounding skin and the arrest of wound secretion. According to the authors, all of these objections are negligible.

The solution has been used with unmistakable benefit in gas gangrene and in compound fractures complicated by infection. In disintegration of joints in compound fractures of the skull in empyema and after inflammation or wounds of the abdominal cavity, eusol has been of benefit in preventing suppuration and arresting infection. A number of cases of acute toxemia subsequent to wound infection with a gas producing organism have been treated by intravenous injection of eusol in amounts

varying from 4 to 70 ccm. to which was added sodium chloride in the proportion of 0.85 per cent. With this method of treatment most gratifying results have been obtained. E. K. ANASTOMO.

Clinical Report on the Application of Eusol; Report to Medical Research Committee. *Lancet* Lond 916, ccc, 356.

The Medical Research Committee of the Royal College of Surgery of Edinburgh has presented a very interesting report on the use of eusol in the treatment of wounds. Several cases are cited to illustrate the use of the solution in both aseptic and septic wounds and to illustrate its value in serous and synovial cavities and in inflammatory lesions of various types. They advocate its usefulness in wounds which have become septic after certain operations.

Their general conclusions are that eusol in a great variety of cases has proved to be non-toxic and non-irritating, as well as an efficient antiseptic. The action of eusol depends upon the free hypochlorous acid which is liberated by the eusol. There is also a sufficient quantity of borate of calcium to give the solution a slightly alkaline reaction. This feebly alkaline solution can be introduced into wounds or serous cavities with perfect safety. It can even be left in such cavities in quantity without any harmful effect. In lacerated and contused wounds, and in compound fractures, such as are met with in military practice, the committee found it to be the most efficient antiseptic.

It is most efficacious during the period of what might be termed progressive sepsis. Some surgeons have emphasized the benefit of modifying the treatment when sepsis is subsiding or has ceased. The granulations form after a period of two to three days and rapidly cover the surface of the wound. Any tendency to superabundant growth of granulations and consequent delay in healing can be counteracted either by so applying the eusol that the serous discharge is reduced to a minimum and the wound kept dry or by discontinuing eusol and using other dressings appropriate for healing wounds. In any event the sepsis is by this stage completely under control.

The freedom which can be exercised in the application of eusol, and the rapid action which it has in arresting the sepsis and discharge of an infected wound, led to experiments on the effect of eusol on the blood. Following this, eusol was employed in the treatment of general sepsis toxemia by intravenous injection.

This method was first made use of by Lorrain Smith Ritchie and Riddle in a case of grave puerperal septicemia, and the result was the recovery of the patient. They have also applied the treatment in other similar conditions. In several cases toxemia has been successfully overcome, and although such a result has not been uniformly attained, the safety of the method justifies its being applied in the diseases referred to in their pre-

liminary communication. Intravenous injection has also been applied with success by Captain Fraser and Captain Bates in cases of cut toxemia secondary to gas gangrene.

Further research is now being carried out on the development of the subject foreshadowed by these investigations.

The lotion is exceedingly inexpensive. The ingredients are procurable anywhere at a slight cost, and the preparation is a very simple process. Eusol powder is composed of equal weights of boric acid and bleaching powder. The boric acid is in sufficient excess to set free the hypochlorous acid in the solution. The bleaching powder should be dry and should contain 28 to 30 per cent available chlorine.

The solution of eusol is prepared as follows: Add to 1 liter of water 5 grams of the powder, shake well and allow it to stand 24 hours, then filter. The clear solution is eusol, and contains about 0.5 per cent hydrochlorous acid. If the bleaching powder is old or not pure, the strength given above will require a larger quantity of the powder.

A rough and ready method of preparation is to add one half ounce of the mixed powder to a pint of water, stir or shake and allow the sediment to settle. D. C. B. x

ANÆSTHETICS

Jackson, D. E. Some Observations on Anæsthesia and Analgesia. *J. Pharm. Med.* 1 p. Th. p. 96 viii, 3.

Jackson calls attention to the fact that for a number of years past nitrous oxide has been constantly growing in use as a general anæsthetic and analgesic. It has been made possible, in his view, by the introduction of improved methods of administration. The duration of the anesthesia under nitrous oxide has also progressively increased from an average of only minutes or less up to an average of perhaps ten minutes or longer, and Jackson states that he has been able by improved method to keep dogs anesthetized for periods up to five and one-half hours. Quite recently he states there has been a slight tendency to avoid the use of nitrous oxide in any prolonged operation (half hour or more) because it has frequently appeared that the after-effects of prolonged nitrous-oxide anesthesia were more deleterious than those of ether. He believes that this is mainly due to the use of improper and unscientific methods of administering the nitrous oxide. He maintains that the cost of nitrous oxide by the method which he has made use of may be reduced to about 30 or 35 cents per hour for the human subject.

GEORGE L. BELL

Walter W. An Apparatus for the Administration of Gas-Oxygen. *N. Y. M. J.* 90, ccl 352.

A new apparatus is offered which combines simplicity, portability, efficiency and freedom from pres-

sure addition of humidity a curacy the washing of gases the warming of gases visual evidence of the ratio between the gases and a provision for re-breathing with or without either sequence and with out the removal of the mask. The gases are passed through warmed water by means of respective tubes and the evidence of the quantity of gas is shown by the levels of the water in these tubes. A table of ratios is placed in view between the gas-tubes and for any given volume of nitrous oxide as evidenced by the level the desired percentage of oxygen for that particular level may be read and instantly provided by readjustment of the oxygen valve. The apparatus is illustrated and the technique of its application fully described in the original article.

E. K. ARMSTRONG

Aikins, W. H. B.: The Advantages and Risks of Combined Local and General Anesthesia
Can. J. Path. & Clin. Med. 1913 11 37

The author limits his discussion of the use of combined local and general anesthetics to operations about the nose and throat. Hewitt's tabulation of advantages claimed for such a combination are:

- 1 The elimination of the element of fear to which a certain number of anesthetized patients are due.
- 2 The production of a somnolent or apathetic condition which facilitates anesthesia.
- 3 The absence of excitement during anesthetization.
- 4 A diminution of the amount of the general anesthetic necessary to produce the necessary relaxation and depth of anesthesia.
- 5 The diminution of secretion especially that of mucus under ether.
- 6 Lessening of the tendency to vomiting and pulmonary complications.
- 7 Lessening of the tendency to shock.
- 8 A longer period of insensibility after the end of the operation reducing the discomfort and pain.

Adrenalin and cocaine the only local anesthetics considered in this article must be used with great care and discrimination. They should be applied at least one hour before the induction of general anesthesia.

Many authors are quoted who have observed sudden death follow the injection of cocaine adrenalin solutions during a chloroform anesthesia. Dr. Goodman Levy has been able to produce ventricular fibrillation in cats almost at will by injections of adrenalin during chloroform anesthesia a phenomenon which has not followed ether anesthesia. Whether or not the disturbances noted are due to rapid absorption of adrenalin from the sub-mucous tissues or to direct injection into a vein has yet to be determined. But the undoubted risk of using cocaine and adrenalin in combination with general anesthesia induced either completely or in part by chloroform has been definitely proved. The author concludes with an emphatic protest

against such a combination of local with general anesthesia.

E. F. CURT

Hanes, G. J.: Spinal Anesthesia *Lancet* 1913 11 130

The author bases his discussion upon 26 real cases which he has observed. He claims that the advantages of spinal anesthesia over all other methods are that it causes the most perfect relaxation of the parts which it is possible to obtain and that the patient has less post-operative discomfort. In the discussion of the technique the usual points are emphasized: the proper type of needle (short sharp point) an all glass syringe the proper point for injection the upright position of the patient and the proper strength of solution. He has used novocaine in all his cases (one half to one and one half grain solutions being the dose employed).

The operations were for hemorrhoids, tubular structures, polyp, ulceration, ne colostomy and three aneura. The colostomy case was not sufficiently anesthetized with one half grain novocaine to permit the operation to be completed without the addition of ether. One patient who was operated upon because of a great deal of pain in the rectum was given one and one-half grains of novocaine. Although kept in the upright position within five minutes respiration had ceased and no evidence of circulation could be observed. Under various stimulants the patient again had good pulse and respiration but he died within twenty-four hours without regaining consciousness. Post mortem examination showed marked disease of all the vital organs which should have been sufficient reason for prohibiting any form of operation. With these two exceptions the author's experience with spinal anesthesia was completely successful and he is convinced of its superiority in rectal operations.

E. FUSCH

Lewis, B. and Bartels, L.: Caudal Anesthesia in Genito-urinary Surgery *Surg. Gynec. Obst.* 1913 11 263

This is the method of anesthesia proposed and first used by Laeven and is based on the use of saline injections into the sacral canal suggested by Cathlin in 1901. It is a nerve blocking method of local anesthesia applied in the sacral canal using a combination of novocaine potassium sulphate and adrenalin as the local sedative fluid. At the time of the making up of the report the authors had used the method in 85 cases and with such success that they felt justified in making the report.

This method is to be distinguished from that of spinal anesthesia in that the solution is not injected into the spinal canal. The spinal canal is separated from the sacral canal by the cuff of dura mater which closes down on the cauda at about the first segment of the sacrum. An injection of fluid therefore into the sacral canal does not reach up into the spinal canal. The object of the injection serves to obtund the sensibility or anesthetize

the nerves issuing from the anterior sacral foramina that form the sacral plexus. One of the most important nerves of this plexus is the pudic, distributed to the bladder and prostate and other genito-urinary organs. By anesthetizing this nerve an anesthetic condition of the organs mentioned is secured.

Directions for preparing the solution are given and the authors' experience with dosage is detailed. It was found preferable to use larger quantities of weaker solution rather than small quantities of stronger solution to obtain the anesthetic effect. It was found that the pressure-effect of the anesthetic fluid was strongly influential in securing success. From 50 to 90 ccm. of the fluid is now being used by the authors.

The method is particularly advantageous in the very debilitated decrepit, and aged patients who require major work in genito-urinary surgery. Prostatectomies done suprapubically, removal of vesical stones, and cystoscopies in hypersensitive individuals, have all been done with marked success and comfort under this method of anesthesia.

The technique of the administration is described and illustrated in the original article. Measures for preventing untoward effects, such as introducing the needle into the spinal canal or into veins, are

described and suggestions given for avoiding such effects.

SURGICAL INSTRUMENTS AND APPARATUS

Bergeson, J. Z. *PILL Compression Forceps for Controlling Hemorrhage Following Tonsillectomy* *J. Am. M. A.* 9 6 14 55

The forceps devised by the author for compression of the pillars after tonsil enucleation, consist of (1) a handle, (2) a lock, (3) a goose neck shank, and (4) compression tips. A compound forceps which has a straight shank is also described but the two are to be used together. The curved forceps to be applied above and the straight forceps below. The curved forceps are so constructed that the handle lays outside of the mouth, sufficiently to the side to permit work on the other tonsil or the adenoids while the compression continues.

The point of chief importance in applying the forceps is to pass the compression tips to a sufficient distance toward the larynx and all of the throat so as to include in the bit (1) that portion of the posterior pillar next to the constrictor of the pharynx, (2) the floor of the tonsillar fossa and (3) that portion of the anterior pillar next to the insertion of the hyoid. OTTO M. ROY

SURGERY OF THE HEAD AND NECK

HEAD

Gray H. M. W. *Observations on Gunshot Wounds of the Head* *Brit. M. J.* 9 6 1, 16

The principles in the treatment of these wounds as deduced by Gray are as follows: (1) Infected gunshot wounds of the skull and brain require more careful consideration and prompt attention than similar wounds of any other part. (2) Septic can best be combated and prevented by early and complete operations. (3) Permanent disability can be prevented in most cases by the systematic removal of foreign material or displaced bone from the surface or substance of the brain whenever these are accessible to legitimate surgery. (4) By these precautions the immediate results in the saving of life and more rapid restoration of function, when possible, are better than those obtainable by more conservative procedures.

The presence of any foreign body in the brain may not cause immediate disability but sooner or later the brain is very apt to resent the presence of these bodies and untoward symptoms develop. Fragments of bone, clothing, metal, etc., should therefore be removed as soon as possible after the receipt of the injury. The presence or absence of cerebral or cerebellar symptoms should not in the average case, deter the operator from the radical treatment of these wounds.

In minor injuries the lacerated scalp should be excised and sutured. Primary union usually results.

In depressed fractures of the inner table contusion of the brain is almost certain to occur. The dura should be opened in all such cases even when it is apparently normal otherwise injuries to the brain substance may be overlooked and scar tissue forms which may cause future trouble. Furthermore the injured brain substance if allowed to remain untouched may become infected and cause abscess, encephalitis, meningitis. When wounds of the blood sinuses are present it is thought advisable to remove depressed fragments of bone for two reasons: (1) Their retention may cause obstruction to the return of blood from some part of the brain or (2) may lead to septic thrombosis.

As to drainage of the brain, as a general rule this should be avoided whenever possible. The presence of definite pus, infected blood-clot or inaccessible definitely infected foreign bodies, or profuse oozing would indicate drainage. Bacteriological examination of removed substances should be made and if streptococci are found the drainage should be maintained until these disappear from the discharges or become very few in number.

Several points are enumerated by the author: (1) There may be multiple injuries, therefore the whole scalp should be shaved. (2) The force causing the injury usually results in local injury; injury by contre-coup has rarely to be considered. (3) Fracture of the inner table almost always means injury to the brain substance. (4) A complete

operation facilitates repair gives better immediate results and tends to prevent troublesome sequelae more surely than an incomplete one. (5) Death is due in practically all cases to the effect of sepsis on the damaged brain. (6) The aim in all operations should be to remove as much infected material and tissue as is feasible. (7) For ign bodies act deleteriously in four ways by direct effect on delicate brain substance favoring sepsis interfering with circulation and causing scar formation. (8) It is highly important to prevent scar tissue formation whether on or in the brain. The nature of the injury, the amount of sepsis, the presence or absence of foreign bodies and the treatment employed have much to do with the amount of scar formation.

The routine of treatment is as follows. On admission the patient's scalp is shaved, the wound thoroughly examined and two skiagrams taken at right angles to each other and an exhaustive neurological examination made. An aperient is given and urotropine given. If the brain is exposed operation should be done at once and in no case should operation be postponed longer than two days.

The majority of wounds of the scalp should be excised and the bone beneath carefully examined. If no bone injury is found the wound can usually be sutured and primary union almost always follows.

Depressed fracture demands immediate exploration. Some cases without injury to the external table may have fracture of the internal table usually suspected from the location of wounds or the clinical findings. Where the dura is normal in appearance and the brain pulsates well it may not be necessary to open the dura. When the dura is muddy looking and the brain does not pulsate it should be opened up by means of a crucial incision. The useless brain material will usually exude.

An injury to the dura without foreign body or sepsis requires careful trimming of the dura, the lost tissue being replaced by a piece of aponeurosis and the scalp sutured. Where a foreign body or sepsis accompanies the injury its withdrawal is attempted and drains usually inserted along the track.

Injury to the blood sinuses can often be closed by the application of a small piece of aponeurosis. The opening is carefully cleansed and the small piece of fascia then quickly applied.

Lumbar puncture has given relief from persistent headache in many cases but ordinarily no more than 10 ccm should be withdrawn. J H SKILES

Cook, F. S. Bone-Transplantation in Nose Deformities. *Br J M J* 916 21 49

Three cases are reported in detail where bone deformities were corrected by bone transplants. The technique is as follows. A curved incision is made at the root of the nose and the skin dissected free clear to the tip. The periosteum is then raised and raised. A piece of rib (ninth) is then inserted

with its periosteum still attached and sutured in place. The skin is sutured and the stitches removed on the fourth or fifth day. The author claims very good cosmetic result. J H SKILES

Mathews, F. S. Calculi in the Submaxillary Gland and Wharton's Duct. *J M S* 1914 12 11 1430

The author reports 18 cases of calculi in the submaxillary gland and in Wharton's duct, which confirm the rarity of the lesion in an unusually large number. Two of his cases presented the usual symptom of pain and swelling at intervals especially at night, showing the bulbous enlargement of the stone. In others without a preceding history there suddenly appeared inflammation and swelling in the submaxillary region as on parotitis, a high fever not unlike mumps. One case had a hard swelling under the jaw and a high rounded mass of the tissues of the floor of the mouth. Unless the stone is very small it can be readily palpated by manually ven in the presence of considerable swelling. All of these cases made a complete recovery after the removal of the stone under no anæsthesia, the stone passing through the mouth either by dilating a sinus or in passing the duct over the stone. The presence of multiple stones must not be overlooked as a second stone frequently exists. (1914 12 11 1430)

Kazanjian, V. H. Treatment of Maxillary Fractures. *Br J M J* 916 366

These fractures are usually compound and the treatment of the wound is very important but not related especially to the discussion at hand.

The aim is to maintain a comparative immobility of the parts. All the available devices may not be sufficient to affect this condition when much bone destruction is present.

The ordinary case is treated by firm bandage with wiring of the teeth if such is necessary. The care of the mouth is important and antiseptic douches and applications are recommended. The most dreaded complication is hemorrhage. A slight oozing may be the beginning of a serious hemorrhage and should be carefully followed up. J H SKILES

Cole, P. P. and Bubb, C. H. Deformities of the Jaw Resulting from Operation or Injury. *Br J M J* 916 1, 263

In deformities from operations on the upper jaw conditions may be present which require one or more of the following procedures: (1) an attempt to separate the nasal from the oral cavity (2) to restore the masticating surface and (3) to restore the facial contour. The apparatus is usually made of vulcanite and is held in position by aluminum plates.

In simple division of the lower jaw a suitable splint may help in coaptation of the ends. When part of the mandible has been removed the lateral gliding shoes of Lehnert are recommended. When

o e-half of the mandible is removed a modified Gunning splint may prove useful. J H. SKILES.

Weil, R. The Treatment of Parotid Tumors by Radium. *J Am M Ass* 9 5 100 32.

Although recent literature contains accounts of parotid tumors favorably influenced by radium, yet as these tumors are of different types and no information has been given as to the microscopic structure, definite deductions cannot be drawn as to the particular type or types of parotid tumors which are suitable for radium treatment. The case now reported by Weil has reference to a tumor of this kind of seven years' duration, which was histologically examined and classed as adenoid cystic epithelioma. The general type of the tumor was that which Billroth named cylindroma.

The treatment consisted of the insertion of radium into the tumor for six weeks at the end of this period it had disappeared and after an interval of almost two years there is no sign of recurrence.

HOLZLI E. POTTER.

Morestin H. Repair of Losses of Frontal Substances by Means of Cartilaginous Transplants (*Réparation des pertes de substance du frontal à l'aide de transplant cartilagineux*) *Bull d mem Soc de chir de Par* 9 6 211, 212.

Morestin reports the operative details of two rather extensive breaches in the frontal regions repaired by cartilaginous transplants. The technique is relatively simple and the results in such cases are constantly favorable. The cartilage is better taken from the subject himself but it may be borrowed from another operated subject.

In Morestin's first case there was an osseous loss about the size of a five franc piece in the right frontal region between the eyebrows and the root of the nose. After a series of plastic procedures to restore the symmetry of the parts, the breach was finally filled with cartilage taken from another patient.

In the second case where there were also very extensive losses and the right eye had been enucleated, the repairs were effected by material removed from the region of the seventh and eighth costal cartilages of the patient's right side. In both cases excellent results were obtained.

The work is very delicate as it involves reconstruction of the interior part of the upper orbital arcade and the frontal region corresponding to the root of the nose.

W. A. BERGMANN.

Landry L. H. Intracranial Hemorrhage Due to Traumatic Rupture of Arteria Meningea Media; Report of Six Operated Cases with One Death. *South M J* 9 6, 1 57.

It is estimated that 90 per cent of meningeal poplexes prove fatal if unrelieved surgically while of a large series of operated cases 67 per cent recovered, a percentage which would have been much larger had it been possible to secure intervention before the onset of medullary symp-

toms. All statistics favor operative relief those of Bergmann being the most convincing, so successes in 33 operations. The great majority of extradural hemorrhages occur in the lateral aspect of the skull, particularly in the temporal region, those of slight degree not causing symptoms of compression. Ashurst found that a clot between the dura and the bone equaling one-twelfth the capacity of the cranium will produce coma and death in a few hours. The most common source of the bleeding is the torn anterior branch of the middle meningeal artery. Occasionally the hemorrhage has been sought for on the opposite side while in reality it was on the same side as the existing cerebral manifestations at the extremities. The author believes that compression of the opposite side accounts for the collateral paralysis.

Usually the patient is so stunned from the injury that a degree of unconsciousness is produced, from which he recovers only to show evidence of cerebral disturbance headache possibly vomiting and stupor. This free interval was marked in four of the author's cases but was absent in the first two. In the clinical picture medullary symptoms are invariably present the blood pressure is high pulse slow respiration is labored later it is of the Cheyne-Stokes type and finally the paralytic stage of compression supervenes.

Compression from any cause must be removed, whether from depressed bone or epidural hemorrhage. If given proper attention the most terrible injuries of the skull will go on to a good recovery. It is safe to say that in any serious cranial injury in which unconsciousness has been present from the first subdural bleeding is taking place. In localizing the anterior meningeal artery the method of Kronlein is the most acceptable. At the pterion the artery is found passing forward and this point is located by dropping a perpendicular from the bregma to the middle of the zygoma, then drawing a horizontal line back from the external angular process at the junction of these two lines is the Sylvian point the location of the pterion. However the methods of measurement have lost their importance as the surgeon of today explores through a large perture and not by trephining. Usually the injury to the cranial vault is the best guide to the seat of hemorrhage.

The author advocates immediate exploration and decompression in doubtful cases, as such an operation adds no more risk to life and often prevents a fatal outcome.

E. K. ARMSTRONG.

Gosset A. Cranioplasty by Cartilaginous Flap (*Cranioplastie par volet cartilagineux*) *Bull d mem Soc de chir de Par* 9 6 211, 212.

Gosset reports 5 cases of cranial osseous breaches repaired by cartilaginous flaps. Whereas, Morestin, who is the originator of this method usually employs himself several pieces of cartilage in building up and closing the breach Gosset prefers to use one single piece. He thinks this gives better result in

combating pressure from the brain and in the prevention of cerebral hernia W. A. BRYMAN

Frazier C. H. Types of Hydrocephalus Their Differentiation and Treatment 1st J. D. Child 1916 1 95

The author suggests a new classification having a physiological background with direct clinical application

- 1 Hydrocephalus obstructions
- 2 Hydrocephalus nonabsorptus
- 3 Hydrocephalus hypersecretus
- 4 Hydrocephalus oculinus

1 In hydrocephalus obstructions there is mechanical obstruction to the natural drainage of the cerebrospinal fluid from one or more ventricles into the subarachnoid space where the absorption takes place. This obstruction may be due to a congenital defect such as absence of the aqueduct of Sylvius or as is more frequently the case it may be the result of adhesions from a pre-existing inflammatory lesion. If the aqueduct of Sylvius is lacking or closed by adhesions there will be a dilatation of both the third and the lateral ventricles while a closure of the foramen of Munro would cause merely an enlargement of the lateral ventricle on the affected side. If as is often true in cases of high-grade but evenly-distributed hydrocephalus the passage of the fluid through the foramina of Magendie and Luschka is blocked there will be a general dilatation in which all the ventricles participate

2 In hydrocephalus nonabsorptus absorption is delayed or defective as has been proved by the phenolsulphonophthalein test. Whether the restricted absorption is to be attributed to (1) the cutting off of part of the subarachnoid space by adhesions (2) a toxic substance in the fluid which prevents its absorption by the venous channels or (3) whether it is due to an abnormal condition of the agents which transport the fluid to the venous circulation is still a matter of conjecture

3 By a process of elimination and by a careful consideration of the normal physiology of the cerebrospinal fluid and of the possible changes under abnormal conditions the third type with apparent excessive accumulation of fluid has been attributed to hypersecretion—hydrocephalus hypersecretus. Since it has been conclusively proved by morphologic and histologic studies of the choroid plexus by chemical analyses of the fluid by a study of the effect of choroid extract on the secretion of cerebrospinal fluid that the cerebrospinal fluid is the secretory product of the choroid gland it would seem logical to suppose that a pathologic condition of the gland itself or a toxic substance in the fluid coming in contact with the plexus might bring about a hyperactivity of its cells

4 The author includes in the varieties of hydrocephalus a fourth type for which the term hydrocephalus oculinus has been chosen although pathological is otherwise appropriate. The con-

dition thus designated occurs usually in children though occasionally in adults and is characterized by excess of fluid in the ventricles basal system and sometimes throughout the subarachnoid space without there necessarily being any increase in the cranial dimensions. Symptomatically this condition may be more closely allied to tumors but from the point of view of treatment it properly belongs to the prolapsed hydrocephalus in that the essential feature is an excessive accumulation of cerebrospinal fluid in the subarachnoid space

The clinical tests may be summarized as follows

First examination

- 1 Lumbar puncture
- Withdrawal of 1 ccm of cerebrospinal fluid
- 3 Attach a 2 cm. rubber syringe filled with 1 ccm neutral solution of dye
- 4 Withdraw piston until syringe is full
- Inject solution slowly into lumbar subarachnoid space
- 6 Withdraw needle
- Test urine for phenolsulphonophthalein every five minutes until dye is detected
- 8 Estimate the total amount of dye excreted in the first 2 hour specimen of urine

Second examination on the following day or after dye is no longer found in the urine

- Puncture of the lateral ventricle
- 3 Inject 1 ccm neutral phenolsulphonophthalein solution

- 3 Lumbar puncture examine for dye every five minutes until dye appears
- 4 Test five-minute specimen of urine
- 5 Estimate total amount of dye excreted in first two-hour specimen

6 In calculations the amount of dye lost by lumbar puncture must be taken into consideration

The simplest and most effective method of dealing with hydrocephalus obstructivus is puncture of the corpus callosum the Balkenstich of Anton and Bramann

In the non-absorptive type great technical difficulties are encountered with some reservation, because his technique is in the developmental stage the author recommends the establishment of a drainage tract into the pleural cavity. When the lesion is due to hypersecretion he resorts to thyroid feeding. LOWNER & C. KILL

Remsen C. M. The Relation of the Pathological Bases of Hydrocephalus to Its Surgical Alleviation 1st J. M. J. 96 4 15

The condition leading to the development of hydrocephalus may be primary as in the congenital type or secondary to obstruction of the foramina of exit (meningeal adhesions) or of the vein of exit as in brain tumor

Trauma leads tuberculosis sept meningitis brain tumor and chronic alcoholism may be associated with it while tubercular meningitis may lead to fatal hydrocephalus

The author outlines the anatomy and physiology

of the ventricular system and discusses the sources of origin of the cerebrospinal fluid. By means of experimental blockage of the ventricular cavities and stimulation of the choroid plexus the latter have been shown to be the chief origin of the fluid. Likewise other experiments have shown the egress of the fluid to be chiefly by means of absorption into the arachnoid villi and venous sinuses. Hence, an increase in the cerebrospinal fluid may be due to (1) an overproduction by the choroid plexus (2) a disturbance of the principal absorptive system—the arachnoid villi and sinuses or (3) to a mechanical obstruction in the course of its flow from the plexus, through the ventricles and subarachnoid space to the sinuses.

That certain types of this condition (choroid plexus) may be of toxic origin seems probable from the effect of the injection of certain drugs or extracts, since brain, plexus, or pituitary and also muscarine have a stimulating, thyroid a depressing effect upon the secretion. As regards pathological conditions producing symptoms of hydrocephalus, the author points out that large posterior fossa tumors are sometimes without signs of increased fluid tension, and that the important sign of choked disk may not be due directly to the tumor itself but to the hydrocephalus, causing infiltration of cerebrospinal fluid along the optic nerve sheaths and compression of the venous return from the retina. In essential hydrocephalus with no pathological obstruction, vicious circle resulting from excessive accumulation of fluid in the cisterna magna pressing on the veins of Galen which causes increased intracranial pressure and depresses absorptive action is responsible. Forcing upward of the midbrain and plugging of the tentorial opening may also be a factor.

The practical results of obstructive conditions being a cutting off of the secretory from the absorptive systems, it is unlikely that thyroid extract or other therapeutic substances will be of benefit and evidently a communication between the systems must be established. The author mentions the various operations devised for this purpose, and recommends the method of von Brawmann as the simplest. In this a ventriculostomy is performed by the passage of a blunt cannula by way of the longitudinal fissure and puncture of the distended lateral ventricle. The continual escape of fluid into the subarachnoid space equalizes the pressure and conditions approach normal. This operation is indicated both in hydrocephalus of the obstructive type and in essential choroid plexus in infancy, before cerebral destruction has occurred. The technique of the operation is outlined. Flures may be due to closure of the ventriculostomy opening.

HORACE BROOKS

Jacob, F. M. Glioma of the Cerebellum with Metastases. *J Med Res* 1918 9:6 131-95.

Jacob reports the case of a young adult girl with a typical history of brain tumor extending over

period of two years. The autopsy showed a large glioma of the cerebellum which had extended into and obliterated the fourth ventricle and occupied most of the central white matter of the cerebellum. Smaller masses of similar character were distributed upon the ependyma of the lateral ventricle, the central canal of the spinal cord and the leptomeninges. All of these masses were very cellular, unencapsulated, infiltrating and to all microscopical appearance malignant in character. Gland-like and rosette structures were noted in many parts of the tumor. The masses in the ventricle were discrete and had nodular papillomatous structure, but the pia mater of the cerebrum, cerebellum, and cord contained a patchy growth of gliomatous tissue extending over a considerable area involving much of the surface of the brain and cord. He found no masses in any organs outside the cranial and spinal cavities.

From his study the author draws the following conclusions:

Although gliomata of the brain do not invade blood and lymph channels or form metastases in distant organs, they do form metastases in the brain and cord by means of cerebrospinal fluid. The reason for this, he believes, may be found in the fact that glia cells are highly specialized and cannot grow when removed from their natural surroundings.

Even though gliomata of the brain do not metastasize to other organs, many of them, the author thinks, should be considered histologically malignant or at least locally malignant on account of their power of infiltration, rapid rate of growth and the embryonal character of the cells.

GEORGE E. BERRY

Grey E. G. 81 dies on the Localization of Cerebellar Tumors. *J Surg Pathol* 9:6, 1911, 29.

Notwithstanding the comprehensive literature which pertains to diseases of the posterior cranial fossa, the significance of the position of the head and of suboccipital discomfort still remains uncertain. The author has carefully analyzed the symptoms in 60 certified cases of cerebella and extracerebellar tumors from Cushing's neurological service in an attempt to determine a consistent relation between the position of the head and the location of the tumor. About 40 per cent of the cases with cerebellar tumor showed some change in the position of the head while only 7 per cent of the cases with tumors anterior to the cerebellum showed any unusual attitude, and in each of the latter cases the change was slight. The tilting of the head or its rotation in patients with symptoms pointing toward an intracranial tumor is very suggestive of a tentorial new-growth. The attitude has no particular significance in localizing the lesion in one side or the other of the cranial fossa.

Backward retraction of the head occurred in 8 out of the 60 cases and typical opisthotonos attacks appeared in 2 of these cases. As this condition

In the opinion of the author all such cases should be removed even if it involves the ligation and excision of the carotids, and no attempt should be made to dissect the tumor free from the vessels unless it is only loosely attached to them.

Leriche: Resection in the Case of Projectile Wounds of the Neck (*Resection dans les plaies de coude par projectiles de guerre*). *Bull. et mém. Soc. de chir. d. Par.* 96 VIII, 46.

Leriche reports the details in the case of four resections of the neck which he has performed owing to injury of the articulation. Two of these were done within a few days after the injury and the other two were done considerably later. Excellent results were obtained in the last cases, but in the other cases there were defects of lateral movement. Ollier's technique was followed.

In submitting Leriche's report Quénu considers that there are three categories of neck resections: (1) primitive, practiced immediately or in the first days after injury and before there is any infection, (2) early secondary made within a few weeks of injury and (3) late secondary when the acute stage is passed and when only a fistulous trajectory is present or even cicatrization is effected. Quénu thinks that whenever the articulation is involved primitive resection is called for. He reports some cases under each category observed by him with particulars of treatment and results obtained.

W. A. BRIDGES

Eames, J. S., Middleton, W. S., and Smith, A. J. Tonsillar Endamebriasis and Thyroid Disturbances. *Am. J. Hyg.* 96 VII, 2.

The authors discuss the etiological rôle played by an endamebic infection of the tonsils in endemic goiter and give a summary of the present-day conception of the part that is played by chronic infections in the causation of goiter, quoting the work of McCarrison on endemic goiter in India, his opinion being that one of the etiological factors is infection of the intestines from drinking water. He showed how the boiling or filtering of water rendered it innocuous, whereas the feeding of unboiled water to non-goitrous patient was followed by thyroid enlargement.

Farrant is quoted as advancing the first definite evidence of specific bacterial agent proposing the theory and evidence of a mutant colon bacillus in the intestinal tract as an important factor in goiter production through the agency of its toxins. He also quotes Halstead and Billings' views on the part that infections play in the causation of thyroid enlargement.

The authors do not hold that infection is the only factor in goiter but put forth the idea that it is one of the numerous agencies that may influence the development of the disease.

A statistical study was made at the Medical Clinic of the University of Wisconsin, with reference to coexistent infections of the nose and throat in their association with goiter. Of the 1,328 men

examined 27 per cent had thyroid involvement of 363 goitrous individuals examined 90 per cent had nasal and tonsillar infection. In tonsils of 34 cases examined microscopically 97 per cent were found to have endamebic gingivitis (Gross) in the tonsillar crypts. Of 6 individuals of this group who after treatment by emetin hydrochloride were re-examined, 8 per cent were shown to no longer have the organism in the crypts contents. In 23 individuals, to whom emetin was administered a reduction in the bulk of the goiter was appreciable in 8 and in 7 dysthyroid cases included in this group of the cured cases, 6 were benefited in degrees varying from slight amelioration to apparent cure.

Inability to demonstrate endamebic in the thyroid gland renders improbable any direct causal relation of the amebic infection of the tonsils *per se* upon the development of thyroid disturbances. The improvement morphologically and symptomatically in the treated cases leaves little doubt after ruling out vasomotor influence from the emetin employed as to an indirect relationship. A symbiosis of endamebic with appropriate bacteria, leading to the elaboration and absorption into the thyroid of selective thyrotoxic poisons via the blood stream is at least conceivable in explanation of the relation.

It is no sense do the authors care to be understood as advancing hereby an exclusive explanation for all goiters. Other types and their locations of sections capable of producing thyrotoxic toxins, perhaps too toxic substances having a similar influence but derived from metabolic or alimentary fault or even entering the body from without are all possible influences. It is the influence of sympathetic stimulation, however accomplished, to be overlooked. The authors are unable to find, however in any of these lines if thought, any satisfactory explanation of the known occurrence of belts of endemic goiter along certain well-defined glacial drifts.

HARRY G. SLOW

Koch, W. F. The Physiology of the Parathyroid Glands. *J. Lab. & Clin. Med.* 96 I, 399.

After consideration of ductless glands in general and the parathyroids in particular Koch endeavors to elucidate the obscure mechanism of the activity of these glands.

The behavior of the parathyroidectomized dog may he says, coincide with either of two distinct types of symptoms, or with a mixture of these types, in which either may predominate. In one type the dominant feature is over-excitability in the other under-excitability. In the former tonic convulsions are characteristic in the latter we observe peculiar muscular flaccidity and a general depression of the nervous system. In either case a pathological condition develops within a few days after removal of the glands and proves fatal within two to ten days.

Up to the present only one fact which contributes

to the explanation of this pathological process has been advanced it is the discovery by MacCallum that the urines of parathyroidectomized animals contain excessive quantities of calcium and that when calcium salts are injected intravenously into such animals the tetany is immediately controlled. It was shown by Beebe and Berkeley that injections of other salts have a similar though not so marked an effect.

Koch recently found that when the tetany had become uncontrollable by injections of aqueous salt solutions the kidneys had become so pathological as to be unable to functionate normally. Since one of the effects of such intravenous injections is diuretic it may be assumed that one of the beneficial effects of the aqueous calcium injections depends upon increasing the work of the kidney and thus the detoxication of the blood. If on the other hand the value of calcium depends upon the increasing or maintaining of a certain reaction of the blood the acid radicals are here the important factor. They present two possible modes of activity: the simple neutralization of basic substances excessively elaborated within the body or the destruction of such substances as are capable of producing them.

There are then several indications that the tetany of parathyroid insufficiency is due to an intoxication namely that it is subdued by increased diuresis and by the neutralization of toxic factors or the destruction of a toxin by acidity. That the origin of the hypertheoretical toxin substance is the body itself that it is useful and not toxic in the presence of the parathyroid glands and that it is filtered through the glomerulus of the kidney point to a substance hormone like in nature and therefore very unstable chemically.

In the effort to ascertain the presence and identity of such a substance the urines were collected separately from 4 parathyroidectomized dogs. Especially designed cages were used to avoid fecal contamination. The urines were filtered and evaporated to a syrup by an electric fan at a tem-

perature not above 30 C. The residues were dissolved in alkali filtered and evaporated and this process repeated until the last evaporate dissolved readily in alcohol. The lipoids present were extracted with ether and the residue taken up in water. This solution was cautiously precipitated with picric acid. Several insoluble picrolonates were thus obtained and by recrystallization from water and alcohol were purified. These substances were retested physiologically. To one of them were added to the blood pressure when injected intravenously into anesthetized dogs. When injected intraperitoneally into non-anesthetized animals they exhibited very marked toxic effects. Because of the agreement in chemical and physiological properties he considered the substance identified as methylcyanamide and trimethylmelamine.

Physiological tests were made with methylcyanamide isolated from the urines and the synthetic methylcyanamide then injected intraperitoneally in non-anesthetized dogs. These were found to have similar effects. In small doses they produced extreme vasodilatation observed in the reddening of the skin and swelling and reddening of the tongue. Larger doses caused paralysis and convulsions. Still larger doses caused a very rapid death.

The author concludes as follows. The similarity in the behavior of the parathyroidectomized dogs to that of the non-anesthetized animals treated with the substance isolated from the urine is further indication that this substance is responsible for the symptom-complex of parathyroid insufficiency. The data therefore justify the following conclusions:

1. Somewhere in the body methylcyanamide is generated.
2. This substance has a physiological value in normal animals.
3. After parathyroid extirpation the substance accumulates to toxic quantities and is responsible for the death of these animals.

ALBERT EHRENFELD

SURGERY OF THE CHEST

CHEST WALL AND BREAST

Perreau H. Penetrating Wounds of the Chest in Warfare. *Med Press—Cr.* 1916 4, 100

A penetrating wound of the chest requires immediate immobilization of the chest. The diagnosis should therefore be made as soon as possible and doubtful cases should be treated by immobilization also as it can do them no harm and may even expedite healing. The early diagnosis is greatly assisted by the roentgen ray.

The immediate immobilization of the chest is necessary to avoid severe complications. Among these complications may be mentioned (1) Embolism which may be caused by any sudden movement

even after a considerable lapse of time and which may prove rapidly fatal. (2) Pleural effusion is very common and may change to a purulent fluid. (3) Subcutaneous emphysema may occur either local or more or less general. (4) Bronchopneumonia and hemorrhage are rare complications. In order to lessen the liability to these complications immediate absolute and prolonged immobilization is necessary.

The conclusions reached by the author are as follows:

1. An early diagnosis should be made by the aid of radioscopes whenever possible.
2. Immediate absolute prolonged immobilization should be ordered.

3. The patients should be kept on a water diet for the first two or three days, not allowing them to raise the head to drink.
4. Such patients should not be transferred until after a fortnight's immobility.
5. During the first four or five days a daily dose of 10 cc. of camphorated oil should be given.
6. Except when absolutely necessary no attempt should be made to remove intrathoracic projectiles.
7. Prompt, wide opening should be resorted to to give issue to early copious purulent effusions.

J. H. SKILES.

Boothby W. B. Gunshot Wounds of the Thorax.

Beds. 15 & S. J. dist. 9 6 378.

The author discusses his observations on 2 cases of thoracic injuries out of a total of 441 wounds of all kinds treated in the Harvard Unit. The cases observed fortunately included examples of most of the important thoracic lesions which reach hospital care.

Hemoptysis was present in nearly all of the cases. In some it was very slight, lasting for a short time; in others it was present for many days. It was more apt to be present when the lesion occurred from the larger and irregularly shaped missiles.

Hemothorax is a complication which arises from injury to blood vessels belonging to the general rather than to the pulmonary circulation, such as the intercostals, the internal mammary arteries and veins, and the azygos veins. These vessels are not surrounded by muscular tissue, hence the tendency to hemorrhage from them. An additional cause of hemothorax is due to the fact that the blood shows no greater tendency to clot when it is in contact with the endothelial lining of the pleura than it does when in contact with the endothelium of the blood-vessels. Toennissen found that at first the fluid was dark red, with a cell count essentially similar to that of blood, but with fewer red cells and a higher percentage of eosinophiles. The fluid had no tendency to clot in the pleural cavity or when withdrawn. When the vessels had finally stopped bleeding the fluid became brighter red, with a decrease in the number of red cells, though the white cells remained the same. The percentage of eosinophiles gradually increased, as much as 70 per cent. The fluid while showing no tendency to clot in the pleural cavity clotted when withdrawn. During the stage of absorption the fluid became less hemorrhagic and at times almost entirely serous. At this stage it gain lost its clotting power when withdrawn from the pleural cavity.

Pensoldt states that at first the blood is defibrinated, and later as pleuritic irritation develops, an increase in leucocytes occurs with the development of a new blood-clotting substance from the pleural endothelium. When the fluid remains long enough in the pleural cavity this clot-producing substance gradually disappears with the pleural irritation. The presence of the eosinophiles

is due to some local cause as they are not present in increased number in the circulating blood.

Sauerbruch has pointed out that bleeding from lung tissue, or the vessel of the pulmonary circulation is of short duration. The lung tissue itself seems to possess a hemostatic action; the early clotting of blood is also favored by the low pressure existing in the pulmonary system of vessels, and lastly the vessels of the pulmonary circulation are surrounded by a loose tissue which on injury contracts down on the bleeding vessel.

The most important principle in the treatment of hemorrhage is *absol. rest* which favors low blood-pressure and clotting. Since it has been shown that late bleeding is apt to occur in from eight to fourteen days after the injury, it is better to allow a period of rest of two weeks to elapse before extended transportation is undertaken.

Out of 84 post-mortems observed by Bradford and Elliott at Boulogne in which death resulted from chest wounds, 60 had effusion of blood in the pleural cavity. 3 died of complications like purulent bronchitis, paraplegia, or abdominal lesions. 46 died from hemothorax, in 38 of which infection was present. Death from hemorrhage resulted only in one case.

In one group of 168 cases of hemothorax treated clinically 114 were sterile and 48 had such large effusions that it was necessary to aspirate. Twenty-eight infected effusions survived after resection of rib. Twenty deaths were due to infection.

In a second group of 60 cases 63 remained sterile and of these 4 required aspiration, 53 cases were infected and survived resection of rib. Out of 1 deaths 16 were infected. There was one death from simple hemothorax.

The foregoing statistics show the dangers of infection in hemothorax. The authors insist on rest of three days after the receipt of the wound. The patient is then taken as rapidly and comfortably as possible to a place where surgical work may be undertaken with safety.

Aspiration to remove part of the fluid and to thereby hasten absorption should not be delayed unduly since the presence of hematoma favors the formation of dense pleuritic adhesions with time. The military surgeon is often prevented from operating with safety in field practice but whenever he commands his environments for aseptic work the rule of aspirating early rather than late should be practiced. The presence of increased temperature which prompts aspiration is not always the result of sepsis. The rise may be due to absorption of fibrin and it may be further aggravated by respiratory embarrassment and mental worry. The rule is to aspirate in all cases of irregular temperature and to practice thoracotomy whenever pus is found.

When aspiration becomes necessary the amount of fluid to be withdrawn is a debated point. Sauerbruch believes that this should not exceed 50 to 100 cc. If too much fluid is removed the intra-

pleural pressure will be lowered and there will be a tendency to recurrent hæmorrhage. In order to avoid this danger it is better to aspirate with a simple aspirating needle to which is connected a rubber tube 30 cm. long the whole of which is filled with sterile water and the distal end immersed in a basin of sterile water. This method produces a suction equivalent to the difference in the level between the surface of the water in the basin and the level of the needle which may be varied up to 30 cm. This amount of suction can be practiced with safety. The method is less risky than the use of an aspirating bottle and pump with which a negative pressure of considerable amount may be produced by the pump.

In pneumohæmothorax air present above the level of the liquid generally disappears rapidly unless there is a permanent communication with a bronchus. The latter adds to the danger of sepsis and when sepsis ensues thoracotomy is in order.

Cardiac injuries are treated by absolute rest and morphia given in sufficient quantities to keep the patient drowsy. Immediate operation is rarely possible under field conditions at the front. The service that preceded the Harvard Unit removed a bullet by operation that lay free in the pericardial cavity. The patient recovered in spite of an empyema following the operation.

All cases with a patent opening in the pleura become infected. The frequency of infection depends largely upon the character of the missile and the condition of the patient's skin and clothes. Infections are more frequent in proportion to the distance from the front. One observer saw empyema in 3 out of 28 cases, another 2 out of 43 cases. Tullier saw infections develop most frequently after shell wounds and when a foreign body was lodged.

Some observers point to the resistance of the pleura to infection as shown in repeated instances of infected external wounds leading to the pleural cavity in which the pleural wound closed thus warding off infection. It is generally agreed that the pleural membrane and the extrapleural fibrous tissue are very resistant to the passage of infection from the extrapleural to the intrapleural surface. Nevertheless care should always be taken not to open the pleura in cases of large septic hæmatomata that develop extrapleurally and which are not connected with the pleural cavity.

When thoracotomy becomes necessary it should be done at the most dependent part of the cavity and the opening should be large enough to admit the hand for thorough exploration and to remove foreign matter. Such a procedure wards off empyema and enables the operator to remove lodged missiles embedded in lung tissue near the surface.

The author concludes his article with the following summary:

1. Intrathoracic hæmorrhage is most likely to cease when the patient is absolutely at rest; therefore he should be kept in bed (under morphia if necessary) at the first available station.

2. Symptoms rapidly developing suggesting pneumonia with marked dyspnoea are probably due to the production of a large hæmothorax or a pneumothorax. Such cases should be aspirated and sufficient fluid withdrawn to relieve dyspnoea. Care should be taken not to produce a negative pressure within the thorax by the use of an aspirating bottle. A simple needle with rubber tube 30 cm. long filled with sterile water and the open end immersed in a basin of sterile water will produce as great a suction as it is safe to use. With such an apparatus as much fluid can be withdrawn as will run out of its own accord.

3. After three days the danger of infection exceed that of hæmorrhage. Therefore if the patient is not in a place equipped for diagnosing and operating for empyema he should be removed to the nearest hospital so equipped and kept there for at least two weeks.

4. Whenever the patient presents an irregular elevation of temperature exploratory aspiration with a small hypodermic syringe armed with a long needle of large bore should be performed.

5. When ver the pleural fluid is found infected a long thoracotomy opening should be made and free drainage instituted.

6. If the patient is in a dangerous condition prolonged search for the presence of a foreign body should be deferred. However all foreign matter should be removed as soon as possible in order to hasten the final closing of the wound.

L. A. LAGARDE.

Herrick J. F. Enlarged Thymus in Infancy

Surg. Gynec. & Obst. 9: 6 Feb. 1933

The symptoms of enlarged thymus may manifest themselves within a week after birth. The symptoms are very similar to those of a foreign body in the air passages. The respiratory difficulty may manifest itself in all possible grades, from a mild stridor to very severe dyspnoea with fatal termination. The symptoms may be the result of pressure on the trachea on the large vessels or on the right auricle as appeared in one of the following cases. The diagnosis is aided by more gradual onset in increasing trouble, absence of X-ray evidence of foreign body with X-ray shadow of enlarged gland, broadened sternal dullness, negative laryngoscopic findings and failure of intubation to relieve. The child is usually well nourished but the complexion is usually pale and pasty. There is no disturbance of pulse or temperature. The treatment may be surgical or X-ray. The former is at times followed by death. The latter is safe and effective.

Six cases are reported. Case 1, aged 1 year, died under anesthesia. In an effort to locate a foreign body, autopsy revealed a very large thymus overlying the right auricle, no foreign body present. Case 2, aged 3 years 7 months, symptoms present since the child was 3 years of age. The child died suddenly without treatment. Case 3, aged 6 months, symptoms began when child was ten weeks

old Symptomatic treatment only was given. The child was living but in a serious condition when 6 months of age. Case 4 aged 4 weeks symptoms present since two weeks of age, attacks very severe. Treatment with X-ray was followed by recovery. Case 5, aged 8 months symptoms present since first week after birth. Treatment by X-ray recovery. Case 6 aged 2 months symptoms present since first week of life. Treatment by X-ray recovery.

TRACHEA AND LUNGS

Villeon, P. de la. The Surgical Extraction of Intrapulmonary Projectiles, Superficial and Deep, Under the Screen by Simple Rapid, and Certain Means (L'extraction opératoire des projectiles intrapulmonaires, superficiels et profonds, sous l'écran, par un procédé simple rapide et sûr). *Bull. Acad. des méd. Par.* 9 6 1914 75.

Thoracopneumotomy for the extraction of intrapulmonary projectiles has been practiced by the author with uniform success.

He also uses a method much simpler and more rapid which was carried out successfully in 20 cases.

The principles of this new procedure are based on the method for using the radioscopic screen for the extraction of intrapulmonary projectiles, which was originated by Madaire. Villeon's technique is different from that of Madaire in that it allows the extraction of deep as well as superficial projectiles.

The projectile being located by X-ray the anesthetized patient is placed under the screen, in

dorsal or abdominal position, according to the nearness of the projectile to the anterior or posterior surface of the lung. The projectile makes a shadow on a point of the thoracic parietes. Two or three finger-breadths away in the intercostal space by means of tenotomy or a fine blade a narrow 5-mm. buttonhole incision is made in the skin. Through this incision is introduced a closed forceps (long Pean, long Kocher) or an old style forceps for the extraction of bullets. This forceps passes with difficulty into the narrow buttonhole incision, and following a line oblique to the normal of projection, leads directly to the projectile. It turns aside before it the intercostal fibers, grazes the upper border of the inferior rib (to avoid wounding the vessels) and always closed, goes through the parietal pleura, then the visceral pleura. It then enters the parenchyma where by a gentle handling it is pushed up to the projectile and touches it.

At this moment the X-ray operator intervenes for the second time to ascertain whether the forceps is in the right place. If not to correct the direction. The forceps touches the projectile and mobilizes it. The forceps then opens gently catches the fragment and extract it as the opening through which the forceps enters the skin incision is very small on withdrawal not a particle of air enters hence no pneumothorax result. The operation lasts but a few minutes, frequently only a few seconds, in difficult cases, 5 to 7 minutes. In simple or typical cases, 4 to 6 seconds. With one suture the buttonhole incision is hermetically closed immediately after the regular dressing is applied. The patient is returned to bed, and receives hypodermic injection of 0.03 cc. of morphine to avoid excitement upon waking and to insure respiratory quiet. In cases of large projectiles, the skin incision is enlarged only when the forceps with the projectile in its blades reaches the skin opening, which can be enlarged as required.

In cases of deep projectiles (8 to 12 cm.) the author employs an old model long bullet forceps.

This sort of instrumentation has given satisfactory results in 6 cases, and only in a very few cases did any air enter the pleural cavity or slight subcutaneous emphysema result incidents without consequence, all of which the author hopes to avoid in the future by using forceps (on the style of Gruenvald) which he is now constructing.

It sometimes occurs that when the lung is free of all attachments, the forceps does not penetrate the parenchyma at the first attempt which occurrence permits of invagination and depression. Slight force may be safely used on the visceral pleura in order to enter the parenchyma. The organ resumes its normal shape and the setting is easily done. The post-operative sequelae are of extreme simplicity. Slight blood expectorations for two or three days thereafter are of importance.

The day following the operation, the patient may sit up in bed. The author's patients left the hospital on the fourth day. In a few serious cases on the eighth day. All cases were devoid of post-operative pyrexia. The fever curve remained at 37°C. All symptoms disappeared in four weeks.

The author never uses costal resection and never has been troubled with pneumo- or hemothorax.

This technique has been used by the author in 6 cases, withdrawing 17 projectiles: 9 superficial 8 deep (6 8 to 12 cm. deep) 6 in fixed lung.

RAOUL L. VIGNAN

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Wallace C. Tabular Statement of 500 Abdominal Gunshot Injuries. *Lancet Lond.* 9 6, 1914, 502.

Wallace gives a very interesting tabulation of 511 abdominal gunshot injuries. The table which is a

large one shows the nature of the operations performed and the character of the lesions encountered. The cases were brought to two field hospitals devoted to the care of abdominal wounds, which were well advanced to within 5,000 yards of the fighting line. Like all statistics gathered so near the front,

the mortality appears greater than one is apt to observe further away on the line of communication. The principal facts obtained may be summarized as follows:

Total number of cases	
Admitted number of	
Total mortalities including hemorrhage	8 per cent
Total mortalities including hemorrhage	14 per cent
Considered hemorrhage upper case	no
No operation considered with side	
Total operation mortality	19 per cent
Total operation mortality	19 per cent
Stomach incomplete mortality	17 per cent
Small gut complete mortality	5 per cent
Small gut incomplete mortality	no

The next table gives approximately the number of times the viscera were injured; the unoperated cases not being included:

	None of H.M.	With H.M.	Total
Stomach	no	no	no
Small gut			
Great gut			
Liver			
Pancreas			
Kidney			
Bladder			
Uterus			
P. area			

In the small gut resection has a higher mortality than suture, but this is doubtless due to greater initial injury among the resected cases. The actual junction line in the resected case rarely gave trouble. Three cases of obstruction were due to non-toxic paralysis. Resection is to be used instead of suture when the saving of time is an object. Contused edges were found to heal well and without slough after suture. The soldier's small intestine is usually empty — the converse is true of the large gut.

Of 23 stomach wounds only 11 were uncomplicated by other lesions; the anterior wall was most often involved; anteroposterior wounds were not common; food extravasation of stomach contents was fairly frequent depending on the time of the last meal.

Of 7 fatal cases of stomach injury, uncomplicated by wounds of other hollow viscera, 4 died as a result of primary hemorrhage. The author dwells on the seriousness of wounds of the epigastric region, and he favors operation in all cases.

The absence of injury to the spleen in stomach injuries was notable and it suggests that such injuries seldom live to reach surgical care.

In the large intestine the mortality was 60 per cent as a result of peritonitis or perhaps more frequently septic infiltration of the retroperitoneal tissue. Wounds of the transverse colon are more apt to be multiple than those of the other divisions of this gut.

Considering the extent of the injury, the wounds of the great gut are much more fatal than those of the small gut, no doubt due to the greater toxicity of the great gut contents.

Most of the injuries of the liver were explored for

hemorrhage. A good many cases might have recovered without operation.

It is suggested that a good many spleen cases recover spontaneously and that it is only when the vessels are torn that bleeding is excessive. The kidney and spleen seem to be not uncommonly injured at the same time while the stomach nearly always escapes.

Walker M. H. Jr. and Ferguson L. M. Peritoneal Adhesions Their Prevention with Citrate Solutions. 1915. Philadelphia 30

The authors have performed more than 100 experiments upon rabbits with the idea of discovering the exact effect of hypertonic solutions of sodium citrate and sodium chloride upon the peritoneum and upon peritoneal adhesions. By careful histological examination of sections made of adhesions taken from one to fifteen days after operation they find the pathology of adhesion formation is simply the process of healing as found where ever tissue has been destroyed.

First an inflammatory exudate of serum and blood is poured out and quickly coagulates. This exudate is composed of fibrin with a few red and white blood-cells in its meshes. The adherent fibrous exudate is the framework upon which the fibrous adhesions are built. Within 48 hours the connective tissue and endothelial cells at the base of the adhesion begin to proliferate. Fibroblasts and new blood vessels appear very rapidly until at the end of a week the adhesion is made up of a fairly dense fibrous tissue containing a moderate amount of blood vessels with no inflammatory exudate. As time goes on the vessels become less numerous and the fibers of the adhesion appear to reach in among the muscle-bundles of the muscle coat of the bowel or of the abdominal wall as the case may be. Meanwhile the endothelial cells of the peritoneum have proliferated and covered the abdominal surface of the adhesion. The final appearance of the adhesion is simply that of a dense scar tissue band covered with peritoneum.

As the result of their experiments the authors conclude that hypertonic citrate solutions do under certain conditions prevent peritoneal adhesions after laparotomy. The best solution is sodium citrate 3 per cent and sodium chloride 1 per cent. Theoretically in human surgery after clean laparotomies a sufficient amount of solution should be introduced into the abdomen to bathe the whole peritoneum (500 to 600 ccm.) and smaller amounts would be of little value.

The authors have not used the solution in human surgery and suggest that the question of shock must be considered and determined by actual tests in the operating room. They believe that if gauze packs used to wall off the intestines are wet in citrate solution much fewer adhesions will result. Adhesions cannot be prevented in the presence of infection by any known method. Large areas of denuded

peritoneum should be covered by plastic operations, for the larger the denuded areas left, the greater the likelihood of adhesion formation. Iodine should be used with great care as very little if allowed to touch the bowel causes masses of adhesions. Dry gauze should not be used inside the abdomen.

G. NEWSON.

Pope, S. The Prevention of Peritoneal Adhesions by the Use of Citrat Solution. *Ann Surg Phila.*, 9 6 1911, 205

Two years ago the author advocated the use of sodium citrate with sodium chloride in solution for the prevention of peritoneal adhesions. His reasons were based upon experimental work done upon rabbits. Since that time with Wallace Terry he has used a solution of citrate of soda per cent with sodium chloride per cent in some 400 abdominal sections. In about 20 cases from four ounces to a pint of this solution was left in the abdominal cavity. In the other cases, the gauze pads and sponges were moistened with the solution. There is no evidence to show that the liability to infection is increased by this treatment, but on the contrary where peritonitis is present, a marked improvement seems to have occurred. The quantity of solution was left in the abdominal cavity of such cases as general post-operative adhesions, acute obstructions, post-tuberculous, colectomies, resections, and tuberculous peritonitis. The abdominal wounds show more oozing during closure in these cases, but in no case was there evidence of post-operative hemorrhage or failure of union. This procedure causes pain and partially rouses the patient so that it has been found expedient to have the incision almost closed before introducing the liquid. Ten of these cases have been reopened so that the benefits could be judged by inspection. The purpose of the citrate is to abolish excessive fibrin deposit with subsequent adhesion formation as it will not prevent inflammatory repair.

GATEWOOD.

Bayne-Jones, S.: Eventration of the Diaphragm, with Report of a Case of Right-sided Eventration. *Arch. Int. Med.*, 9 6, xvii.

The author reports a case of eventration of the right side of the diaphragm. This diagnosis, made from physical examination, was the first of its kind determined during the life of the patient. The clinical impression was confirmed at operation.

The author has collected from the literature 45 cases of eventration of the diaphragm. Of these 3 were right-sided and 42 were left-sided lesions.

In the differential diagnosis between eventration and allied states, the author points out difficulties, particularly with regard to the differentiation from hernia of the diaphragm. He believes that no single method is capable of establishing this differentiation, but the combined methods render the diagnosis reasonably certain.

He summarises the various etiological hypotheses,

showing that the weight of evidence is in favor of the opinion that the disease has a congenital origin.

GEORGE D. BURLAY

GASTRO-INTESTINAL TRACT

Dewis, J. W. Aids in the Diagnosis of Surgical Conditions of the Stomach with Especial Reference to the Characteristic X Ray Appearance of the Syphilitic Hour Glass in Contrast to Those of Simple Ulcer and Cancer. *C. ad M. J.* 9 5 56

The author believes that the greatest single aid in detecting cancer of the stomach and in differentiating this from ulcer is the X ray. It is not easy to differentiate cancer from syphilitic ulcer of the stomach, and even the X ray may fail to detect cancer near the cardia. In the lower two-thirds of the stomach the X ray examination ought to show cancer in every case if properly done and correctly interpreted and in the majority of cases it will detect cancer earlier than clinical methods.

On the other hand to determine whether cancer of the stomach is surgical and when inoperable, while the X ray is a valuable aid the chief means are the ordinary methods and the experience and judgment of the clinician. The author thinks that surgery should be the treatment in all early cancers of the stomach but that the reverse is true in ulcer of the stomach and oedema except where there are acute perforated ulcers.

Regarding chronic ulcers whilst some extreme internists are so convinced of the probability of ulcers healing that they would persist in the medical treatment of practically all ulcers, yet it does not seem likely that an ulcer of the stomach or duodenum with a history of twenty or thirty years duration can be cured within a month or two of medical treatment of any kind.

Chronic ulcers of the stomach become surgical under these conditions when there is chronic pyloric obstruction not relieved by medical means when there is permanent hour-glass contraction in the cases where pain and distress, sour regurgitations, and intractable dyspepsia do not yield to treatment and finally when there are severe hemorrhages.

In syphilis of the stomach the first clue is a history of infection confirmed by the Wassermann test and the X ray. The X ray is most valuable in a differentiative test. Pictures of syphilis do not show the moth-eaten appearance of cancer and there is much more involvement of the stomach wall than in simple ulcer. But the characteristic point that differentiates syphilis from cancer and simple ulcer is that in syphilitic hour-glass stomach a long regular isthmus is seen, at each end of which the walls of the stomach rise more or less abruptly to dumb-bell like. This is in contrast to the sharp incision of simple ulcer hour-glass with practically no isthmus and the picture differs quite as much from the cancer hour glass with the infiltrated walls of the stomach sloping irregularly away from the constricted portion.

HOLLIS E. POTTER.

Squires, J. W. Roentgen Ray Diagnosis of Gastric Lesions. *V. J. M. J. 9, 61*

For the purpose of roentgen ray study the author divides stomach lesions into two groups. The first includes tumors, chronic ulcer, adhesions, and syphilis, lesions which produce permanent defects in the stomach's contour. In the second group are included acute simple ulcer and exudative lesions or lesions which produce a temporary change in the stomach's contour. In either case a positive diagnosis cannot be made without the aid of the roentgen ray.

In early carcinoma the radiographic findings are very similar to those in ulcer, and at this stage it is impossible to determine by the X-ray whether or not malignant degeneration has occurred. From an X-ray standpoint, however, the important line of division is not between benignancy and malignancy, but to determine whether the lesion has advanced sufficiently to be in a surgical case. This stage is determined by the production of permanent defects in the contour, six-hour stasis, and interruption of normal peristalsis. The author emphasizes the importance of careful observation of gastric ulcers in the precancerous stages, as on its early recognition depends successful treatment.

Radiograms are taken immediately after a test meal and every half hour after or even more frequently until sufficient data are obtained. This is followed by fluoroscopic examination.

The diagnosis of gastric carcinoma requires a very careful consideration of the radiographic and fluoroscopic observations. The characteristic findings in order of importance are: (1) filling defects, (2) absence of peristalsis in part involved, (3) mobility, (4) superimposing test, (5) pain at site of filling defect (fluoroscopic), (6) changes in the pylorus, (7) residue, and (8) advanced position of test meal in six hours.

The filling defect is the most valuable as it is constant and is not affected by stomach peristalsis.

The various characteristic findings are shown in illustrations accompanying the article.

The diagnosis of gastric ulcer is similarly based on radiography and fluoroscopy. In the case of chronic ulcer the following signs are basic: (1) permanent irregularities in contour of stomach or cap, (2) interruption of peristaltic contractions, (3) in cicatrix, and (4) locating pain directly over defect (fluoroscopic).

HOLLY L. POTTER

Palmer, C. L. The Significance of Certain Roentgenographic Findings in the Gastro-Intestinal Tract. *J. Am. M. J. 9, 61* 493

Normally the stomach can change its position without the help of alteration in body posture. When this mobility of the stomach is lacking it is either due to restraining forces which prevent the movement, or else to lack of power to move. The former is the most frequent cause for lack of change of position of the stomach.

Persistent supraposed stomach is due to a re-

straint and not to lack of power. This restraint is most frequently exercised by adhesions due chiefly to healed acute chronic appendicitis, traumatic peritonitis, operation, or gastritis due to syphilis and ulcer.

Persistent intragastric distention is not a frequent supraposed stomach. It is usually a by-product of lack of power to move, and is frequently a lack of power which is the cause in chronic gastroenteritis, or with relaxation of the abdominal wall.

Long retention of the gastric contents, twenty-four hours or longer, is due to pyloric anastomosis, an obstruction of the stomach. The other chief cause is long-standing chronic cholecystitis. Retention of a short time, six to twenty-four hours, has for its most frequent cause, cicatricial contraction of the pylorus due to healed ulcer, chronic appendicitis, chronic cholecystitis, phlebitis, and syphilis.

Pylorospasm is local, but it is not always present when extragastric lesions are prevalent. It probably depends on the reflex excitability of the individual nervous system.

Diagnosis is made by judging from the roentgenograms together with the history of the case and other clinical evidence obtainable are correct in nearly every case. This was demonstrated in the majority of the cases by subsequent operation or necropsy. In most of the others it was shown with a satisfying degree of probability by the subsequent course of the case.

Roentgenograms have revealed certain facts which can be demonstrated by other means. The most prominent of these are the obstructive lesions which are as a rule located either in the pylorus of the stomach or in the region of the cecum and are usually due to definite conditions.

By the use of the stomach-tube in gastric analysis, fecal examinations, the charcoal test, Baret's test, and careful analysis of clinical symptoms and physical signs, it is possible in a certain number of cases to make a very accurate diagnosis without the use of the ray. In all cases which are readily diagnosed without the ray, however, roentgenograms should be taken and carefully interpreted along with laboratory tests, clinical history, and physical findings, in order to obtain a clear diagnosis.

Mann, F. C. A Study of the Gastric Ulcers Following Removal of the Adrenals. *J. C. P. M. J. 9, 61* 101

Mann noted at autopsy that animals dying after the removal of both adrenals showed a rate ulceration of the gastric mucosa in a large number of cases, and he states that other investigators have noted similar results. As no lesion of the gastric mucosa was found at autopsy in a series of more than 100 practically normal animals, it seemed to the author that spontaneous ulcers were not common in these animals. He therefore subjected a large series of animals to adrenalectomy, and the results

were studied. The lesions he found in the gastric mucosa after death from adrenal insufficiency consisted of two main types, one a wide-spread superficial erosion the other a true punched-out ulcer formation. The gastric erosions practically always occurred in the fundic division and in most cases, the author states the pyloric mucosa appeared normal. The duodenal mucosa was usually congested in the adrenalectomized animals, and in several instances there were definite ulcers. These duodenal ulcers occurred just distal to the pyloric ring and appeared like cratered areas about 1.5 cm. in diameter. They were deeper at the center than at the edges, penetrating to the muscularis mucosa at the center and they showed no evidence of hemorrhage.

To summarize briefly acute ulcers of the gastric mucosa are found in a large percentage of dogs and cats dying after adrenalectomy. These ulcers seem to develop during the moribund period. They are apparently peptic ulcers forming at the site of local hemorrhages in the gastric mucosa. They are true acute ulcers, usually penetrating to the muscularis mucosa with a total loss of epithellium. They develop in the absence of pancreatic secretion and bile. However they appear to develop only in an acid medium.

GEORGE E. BRADY

Friedenwald, J. The Modern Method of Treatment of Diseases of the Stomach. *Thorp Gaz.*, 9 6 21, 77

The treatment of diseases of the stomach was discussed with regard to the use of the stomach-tube, with regard to the diet, to the use of medicinal agents, of mechanical supports, of mineral water cures, and with regard to surgical measures.

Friedenwald classified the indications for operation under three heads, as follows:

Obstruction. Gastrectomy is indicated in impermeable stricture of the cardiac orifice of the esophagus. In benign obstruction of the pylorus pyloroplasty gastro-enterostomy or pylorotomy is indicated. In malignant disease pylorotomy is indicated for cure and gastro-enterostomy for relief.

Gastric ulcer. The indications for operation are perforation, pyloric obstruction and ulcers resisting medical cure. The operations indicated are excision of the ulcer pylorotomy pyloroplasty or gastro-enterostomy.

Gastric carcinoma. An exploratory incision should be urged in all cases over 40 years of age with manifest symptoms of indigestion which are not relieved by a few weeks of medical treatment and in which the diagnosis is still doubtful after a thorough examination.

J. W. TURNER.

Case, J. T. Roentgen Studies After Gastric and Intestinal Operations. *J. Am. Med. Ass.* 9 5 17, 638.

For several years Case has pursued the roentgenologic study of patients after gastric and in-

testinal operations. The results of this study are given under the headings: (1) Acute small bowel obstruction, (2) gastro-enterostomy, (3) appendectomy and (4) ileocolostomy.

Experience has shown the value of roentgen examination in the diagnosis of post-operative acute small bowel obstruction with special reference to the decision as to the advisability of surgical interference. No barium or opaque meal is usually given, the observations being made by the gas distention of the intestine.

After gastro-enterostomy it has been believed that the rapid exit of food from the stomach was prevented by the formation of rhythmically contracting constriction rings in the duodenum. The author has observed analogous action in a large number of cases in which the ordinary gastrojejunostomy had been performed viz. sort of sphincter action established in the jejunum at a point varying from 3 to 6 cm. below the gastrojejunal anastomosis.

Case says that after gastro-enterostomy there is stagnation of food in the jejunum near the site of the gastro-enterostomy due to the inhibition of onward peristaltic activities at this point.

The occurrence of cecal stasis following appendectomy is very common. Case believes that retention occurs at the site of the stump of the appendix, and that it has some relation to the invaginating suture by which the stump is usually buried.

Most of the cases examined all in fact except those cases in which an artificial ileocolic valve had been formed have shown incompetency of the ileocolic stoma permitting an *enema* to flow back into the small bowel as well as retrogradely around the colon to the cecum as far as the stump of the colon. In long operated cases especially there is very definite ileal stasis.

From his studies Case states that in a very considerable percentage of cases in which the operation of ileosigmoidostomy is performed for the relief of intestinal stasis, the end result is infinitely worse than if the patient had not been operated on at least as far as the stasis is concerned.

H. L. E. PUTNAM

Downes, W. A. Operative Treatment of Pyloric Obstruction in Infants; Review of Sixty-Six Cases. *Surg. G. & Obs.* 9 6 21, 5.

The author reports 66 cases operated upon 1 five and one-half years. All presented the characteristic symptoms. A tumor was palpated in every case before operation.

The theory best explaining the symptom-complex is that a true malformation is present at birth consisting of an abnormal thickening of the circular muscle of the pylorus, and that this is added to an edematous condition some ten days or later after birth. The edema probably results from the increased activity of the stomach necessary to force an increasing amount of food through the narrowed and elongated pyloric lumen.

Gastro-enterostomy was performed upon 31 of the 66 cases the remaining 35 being operated on according to the Rammstedt method. Of the 31 cases in which gastro-enterostomy was done there were 11 deaths—a mortality of 35 per cent. Of the 20 discharged as cured afterwards died of gastro-enteritis and 1 died of diphtheria. The remaining 1 are well and have developed normally. Roentgen-ray examination shows the stomach working satisfactorily and little or no bismuth passing through the pylorus.

Not satisfied with the results from gastro-enterostomy it was decided to try the partial pyloroplasty of Rammstedt. Consequently this operation has been done in the last 3 cases. In this series there were 5 deaths—a mortality of 33 per cent. Of the 3 cases discharged as cured 2 have died in leaving the hospital the remaining 1 are well extending over a period from a few weeks to one and one-half years. In no case has there been a return of the symptoms.

The cases operated on according to the Rammstedt method vomited less and were easier to feed after operation.

The advantages of the partial pyloroplasty over gastro-enterostomy are (1) time consumed for operation the former requiring less than half the time necessary to perform the latter (2) the operation requires much less surgical skill than gastro-enterostomy and (3) the continuity of the gastro-intestinal tract is preserved. Roentgen ray examination one and one-half years after operation and autopsy on one case dying three months after operation demonstrates the fact that the stomach functions normally and that the tumor entirely disappears after this procedure.

Jefferson G. Ulcer of the Duodenopyloric Fornix.

4 5 6 Phila. 910 Nov 18

As is well known, duodenal ulcers have a peculiar partiality for that part of the duodenum immediately adjoining the stomach and the probable rôle of the gastric juice in the production of these ulcers is obvious. The pylorus when viewed from the duodenum appears as a knoblike projection formed by the massive muscular ring which constitutes the pyloric sphincter. The furrow which surrounds this knob is termed the duodenopyloric fornix. The depth of this sulcus varies considerably, being shallow in relaxed hypotonic stomachs and especially well marked in duodenal ulcer where gastric hypertonus is the rule. Owing to the absence of valvular connexions in the suprapyloric duodenum the examination of the interior of this part is relatively easy and it is almost impossible to overlook an ulcer unless it be situated on the posterior wall and hidden by the projecting pylorus.

The author believes that the duodenopyloric fornix is a frequent site of ulcer and that ulcers usually located as pyloric, a term which suggests gastric origin are really duodenal. Chronic ulcers of the stomach rarely in the pyloric canal

and when they become more distant from the pylorus while duodenal ulcers become more frequent as the pylorus is approached. The result of ulcer in this location is the destruction of the usual landmark, making it very difficult to tell the exact point of origin of a duodenal ulcer. Cases are now on record in which the duodenal ulcer has been quite healed while the invasion of the pylorus has become malignant. The great difference in the frequency of antral and follicular duodenal and gastric ulcers makes differentiation extremely important.

GATEWAY

Bryan R. C. Ulcer of the Jejunum

(1) 10 Nov 10

Ulcer of the jejunum is apparently a most rare condition there being only four cases recorded in the literature which arose spontaneously and independent of a previous gastro-enterostomy. The author case was that of a man 45 years old with a history of three years' duration of gastric pain which had been diagnosed as ulcer of the duodenum. He was suddenly taken with severe abdominal pain followed by collapse 12 hours later operation was performed. The stomach was bound down hard and firmly pulled to the left and firm. About 1 inch from the duodenojejunal juncture a round punched-out ulcer about the size of a cherry stone was found. The patient died the following morning.

Diagnosis of this condition apparently must be based upon deduction derived from observation of jejunal ulcers forming after a previous gastro-enterostomy. According to the more recent theories these ulcers develop from autoinfection of the mucosa by an acid action which has been poorly modified by the alkaline products of the upper gut.

This has in a measure been corroborated by the experimental work of Exalto, Kathe, Wullenstein and more recently by Cohen of New York. Willis has done some interesting experimental work on dogs in which he performed gastro-enterostomies administering various amounts of hydrochloric acid thus noting the development of jejunal ulceration. The author is not certain but that there is an association of this condition also with the late
